Executive Summary

Stock

Yelloweye Rockfish (*Sebastodes ruberrimus*) are found from the Gulf of Alaska to northern Baja California in Mexico across the northeastern Pacific Ocean. Their core distribution is from southeast Alaska to central California on the west coast of the United States. Yelloweye Rockfish are strongly associated with rocky bottom habitat and adults are considered to be solitary and sedentary after settlement. Given the general perception of the sedentary nature of Yelloweye Rockfish adults and the moderate amount of mixing that occurs during the pelagic larval stage, the previous Yelloweye Rockfish assessment modeled the West coast population as a two-area assessment (California and a combined Oregon-Washington area) with a common stock recruitment relationship. This update assessment maintains this basic structure.

Catches

Catches for Yelloweye Rockfish have averaged over 20 mt in recent years (Figure i, Table i). Yelloweye Rockfish was declared overfished in 2002 and remains under a rebuilding plan that substantially limits catch. However, as other rockfish stocks have rebuilt and Yelloweye Rockfish has progressed under its rebuilding plan, catches have slowly increased in recent years, primarily in the Oregon-Washington non-trawl fleet and the recreational fleets.

ADW - table es-catches still doubles up the years probably because of the two areas in the model - needs to be fixed

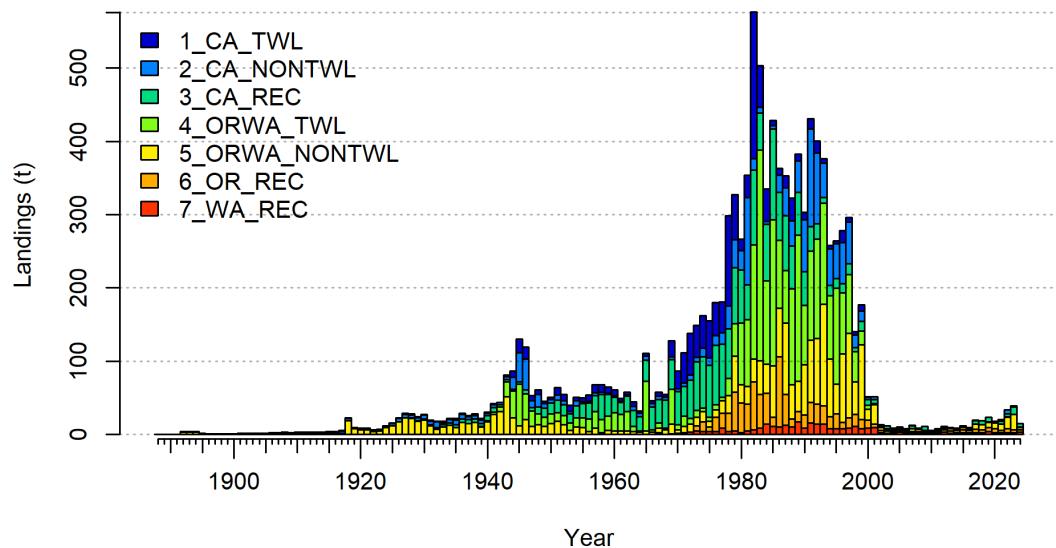

Figure i: Landings in metric tons (mt) by year for each fleet.

Table i: Recent catches (mt) by fleet and total catch (mt) summed across fleets.

Data and Assessment

The last assessment for Yelloweye Rockfish occurred in 2017. This update assessment extends the data used in the 2017 assessment through 2024. Data includes catch, length and age data from seven fishery fleets and multiple indices of abundance in California and Oregon/Washington. Two new historical catch reconstructions from Oregon and Washington were incorporated. Four indices of abundance were updated for this assessment, including two recreational fishery indices in Oregon, the West Coast Groundfish Bottom Trawl Survey (WCGBTS), and the International Pacific Halibut Commission (IPHC) longline survey. In addition, sample sizes and assignment of aging error were corrected in the compositional data. No new data were considered in this update assessment.

Stock biomass and dynamics

The model estimates that the stock was below the minimum stock size threshold in the late 1990s and was lowest in the early 2000s before increasing over the last 20 years (Figure ii). The 2024 relative estimated spawning output is just below the management target threshold.

Table ii: Estimated recent trend in spawning output and the fraction of unfished spawning output and the 95 percent confidence intervals.

Year	Spawning output	Lower Interval (mt)	Upper Interval (mt)	Fraction Unfished	Lower Interval	Upper Interval
2015	263.55	206.64	320.46	0.233	0.198	0.269
2016	273.78	215.04	332.53	0.242	0.206	0.279
2017	285.38	224.61	346.15	0.253	0.215	0.290
2018	297.29	234.27	360.31	0.263	0.224	0.302
2019	310.98	245.40	376.55	0.275	0.235	0.315
2020	326.09	257.63	394.56	0.289	0.247	0.330
2021	343.67	271.94	415.40	0.304	0.261	0.347
2022	362.88	287.55	438.22	0.321	0.276	0.366
2023	382.50	303.26	461.73	0.339	0.292	0.385
2024	402.94	319.54	486.34	0.357	0.308	0.406
2025	426.87	339.09	514.65	0.378	0.327	0.429

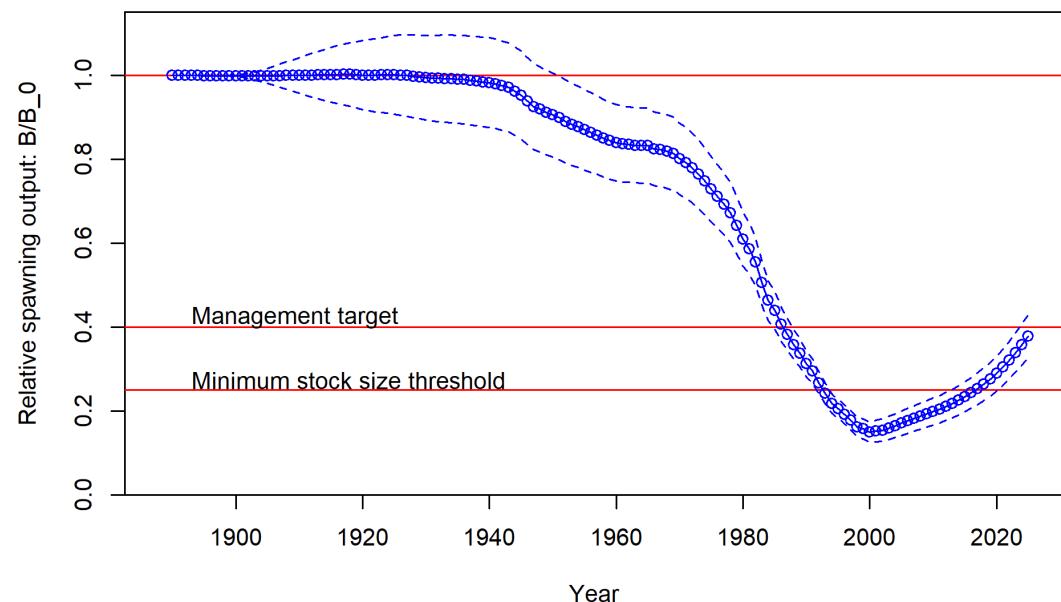

Figure ii: Estimated time series of relative spawning output for the base model.

Recruitment

The largest estimated recruitment events were in 1971, followed by more recently, in 2013 and 2008 (Figure [iii](#), Table [iii](#)). Trends in recruitment are largely consistent with the previous assessment, apart from the most recent elevated time period that is more informed with additional length composition data. Recruits for this assessment appear to have extended this more recent time period starting in 2005, with a peak in 2008 and 2013 and shifts the peak in 2001 to 2002. Recruitment in the late 2010s was estimated to be lower, but a more recent increase is seen starting in 2020.

Table iii: Estimated recent trend in recruitment (1,000s) and recruitment deviations and the 95 percent confidence intervals.

Year	Recruit- ment (1,000s)	Lower Interval (1,000s)	Upper Interval (1,000s)	Recruit- ment Deviations	Lower Interval	Upper Interval
2015	326	183	581	0.711	0.143	1.278
2016	228	120	433	0.328	-0.318	0.974
2017	117	55	249	-0.358	-1.132	0.416
2018	114	53	245	-0.412	-1.205	0.380
2019	119	54	261	-0.390	-1.207	0.427
2020	119	52	271	-0.413	-1.273	0.446

2025	197	78	502	0.000	-0.980	0.980

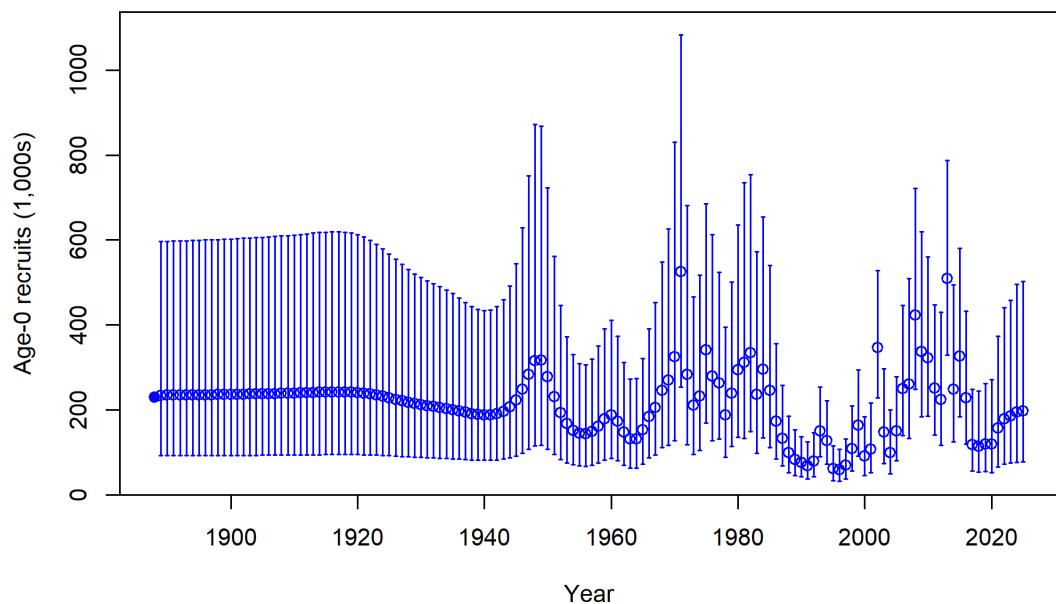

Figure iii: Estimated time series of age-0 recruits for the base model.

Exploitation status

This assessment estimates that the stock of Yelloweye Rockfish off the continental U.S. Pacific Coast is currently at 35.7% of its unexploited level. This is above the overfished threshold of SB25%, but below the management target of SB40% of unfished spawning biomass. Fishing intensity increased throughout the 1900s as the stock was fished down, until stabilizing at peak intensity between the mid1980s and late 1990s and substantially decreasing in the late 1990s and early 2000s. Fishing intensity has since been relatively stable (Figure iv, Table iv).

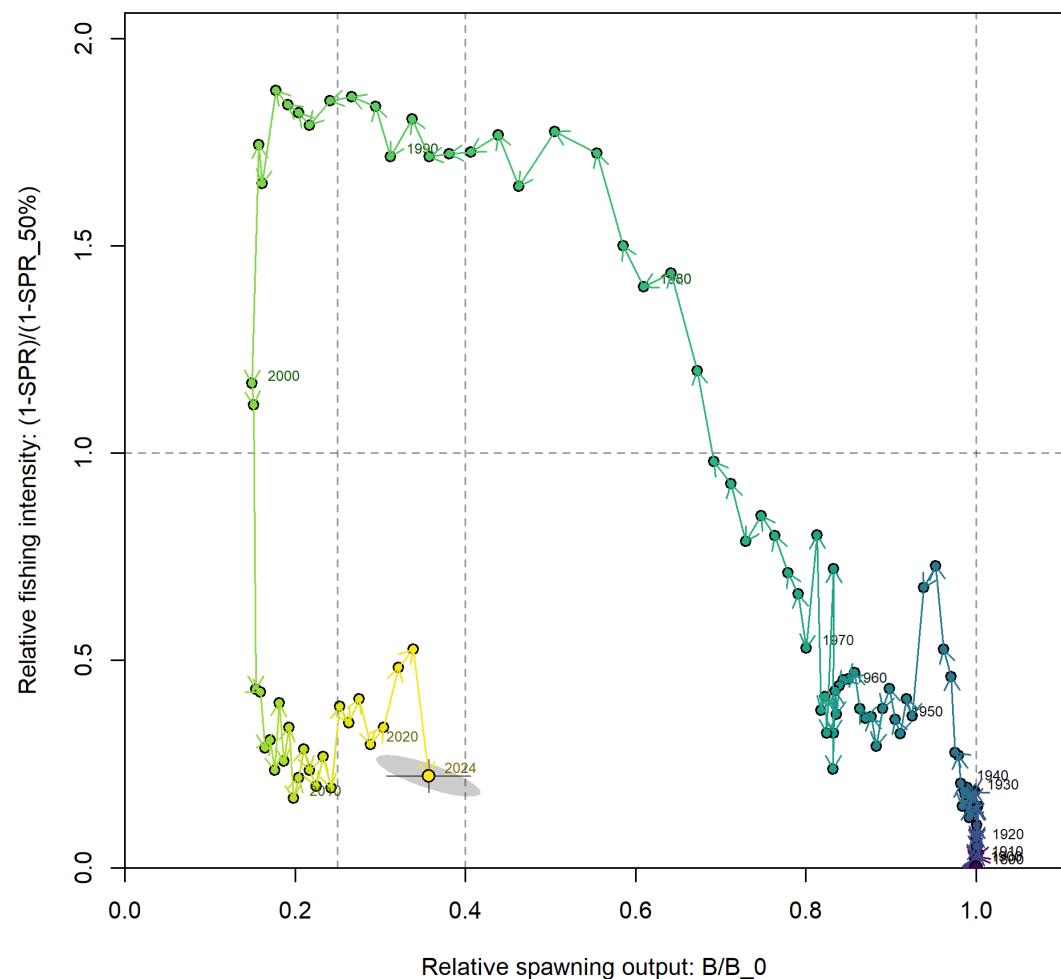

Figure iv: Phase plot of fishing intensity versus fraction unfished.

Table iv: Estimated recent trend in relative fishing intensity $(1-SPR)/(1-SPR50\%)$, where SPR is the spawning potential ratio, and the exploitation rate, along with the 95 percent confidence intervals for both quantities.

Year	$(1-SPR)/(1-SPR50\%)$	Lower Interval (SPR)	Upper Interval (SPR)	Exploitation Rate	Lower Interval (Rate)	Upper Interval (Rate)
2015	0.268	0.220	0.317	0.004	0.003	0.005
2016	0.192	0.156	0.227	0.003	0.002	0.004
2017	0.390	0.323	0.457	0.006	0.005	0.008
2018	0.349	0.288	0.410	0.006	0.004	0.007
2019	0.407	0.339	0.476	0.007	0.005	0.008
2020	0.297	0.246	0.347	0.005	0.004	0.006

2023	0.527	0.444	0.610	0.009	0.007	0.011
2024	0.221	0.181	0.262	0.003	0.003	0.004

Ecosystem considerations

No ecosystem or environmental data was used in the previous Yelloweye Rockfish assessment and no new data were considered for this update assessment.

Reference points

A list of estimates of the current state of the population, as well as reference points based on 1) a target unfished spawning output of 40%, 2) a spawning potential ratio of 0.5, and 3) the model estimate of maximum sustainable yield, are all listed in [?@tbl-ref-points-es](#). Unfished spawning stock output for Yelloweye Rockfish was estimated to be 1129.7 million eggs (95% confidence interval: 999.2-1267.2 million eggs). The management target for Yelloweye Rockfish is defined as 40% of the unfished spawning output (SB40%), which is estimated by the model to be 452 million eggs (95% confidence interval: 397-507), which corresponds to an exploitation rate of 0.025. This harvest rate provides an equilibrium yield of 115 mt at SB40% (95% confidence interval: 101-130 mt).

Table v: Summary of reference points and management quantities, including estimates of the 95 percent confidence intervals. SO is spawning output, SPR is the spawning potential ratio, and MSY is maximum sustainable yield.

Reference Point	Estimate	Lower Interval	Upper Interval
Unfished Spawning output	1,129.7	992.2	1,267.2
Unfished Age 8+ Biomass (mt)	9,803	8,612	10,995

Management performance

Recent trends in total catch relative to management guidelines is available in Table 1 and shows that total catch of Yelloweye Rockfish has remained below both the overfishing limit (OFL) and annual catch limit (ACL) in each year since the previous assessment. Catch in Table 1 combines the two areas in this model as catch limits for Yelloweye Rockfish are managed as a single coastwide unit and includes both landings and estimated discard mortality.

** ADW - this table also doesn't work (doubled years again) - we could switch it to the yelloweye_management csv or fix **

Table vi: Recent trend in the overfishing limits (OFL), the acceptable biological catches (ABCs), the annual catch limits (ACLs), and the total dead catch (landings + discards) all in metric tons (mt).

Year	OFL (mt)	ABC (mt)	ACL (mt)	Total dead catch (mt)
2015	52	43	18	12
2016	52	43	19	9

This section will be updated after GFSC review.

Scientific uncertainty

The model estimated uncertainty around the 2025 spawning biomass for the model is $\sigma = 0.026$. The uncertainty around the OFL in 2025 is $\sigma = 10.82$. Each of these are likely underestimates of overall uncertainty due to the necessity to fix several key population dynamics parameters (e.g., steepness, recruitment variance) and also because there is no explicit incorporation of model structural uncertainty (although see the decision table for alternative states of nature).

Research and data needs

Please refer to the 2017 benchmark assessment for a detailed list of research and data needs for Yelloweye Rockfish (Gertseva and Cope (2017)). In addition to those, the following research and recommendations could improve the ability of future stock assessments to determine the status and productivity of the Yelloweye Rockfish population:

- Continue refining the ORFS index analysis and ultimately use either the ORBS or ORFS index to describe the CPUE trends in the Oregon recreational fishery after 2000.
- Expand the IPHC age composition bins to an older maximum age for the IPHC age composition data to spread out the distribution of length data in the oldest age bins for conditional age-at-length.

Rebuilding projections

This section will be updated after GFSC review.

1 Introduction

Yelloweye Rockfish (*Sebastodes ruberrimus*) are found from the Gulf of Alaska to northern Baja California in Mexico across the northeastern Pacific Ocean (Hart 1973; Love, Yoklavich, and Thorsteinson 2002). Their core distribution is from southeast Alaska to central California on the west coast of the United States (Love, Yoklavich, and Thorsteinson 2002). Yelloweye Rockfish in Puget Sound are considered isolated from the coastal waters population (W. Stewart I.J 2009) and have been listed as threatened under the Endangered Species Act since 2010 (Drake et al. 2010).

Yelloweye Rockfish are strongly associated with rocky bottom habitat, particularly areas of high relief (Love, Yoklavich, and Thorsteinson 2002), and adults are considered to be solitary and sedentary after settlement (Coombs 1979; DeMott 1983). However, new tagging studies suggest that adult Yelloweye Rockfish exhibit larger scale movement patterns more commonly than previously considered (Hannah and Rankin 2011; Rasmussen et al. 2025).

There has been little advancement on information pertaining to the stock structure of Yelloweye Rockfish since the previous benchmark assessment. As noted in Gertseva and Cope (2017), there is evidence of genetic differences between Canadian waters (Strait of Georgia) and West coast coastal populations of Yelloweye Rockfish, but no evidence of differentiation across coastal populations (Siegle and Yamanaka 2013). Gao and Wallace (2010) found that there was complete mixing of offspring from Oregon and Washington waters using otolith isotope analyses, indicating a single spawning stock in this portion of the Yelloweye Rockfish stock. Given the general perception of the sedentary nature of Yelloweye Rockfish adults and the moderate amount of mixing that occurs during the pelagic larval stage, the previous Yelloweye Rockfish assessment modeled the West coast population as a two-area assessment (California and a combined Oregon-Washington area) with a common stock recruitment relationship (Gertseva and Cope 2017). This update assessment maintains this basic structure.

Map of scope of assessment - not needed for update

1.1 Life History

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

1.2 Ecosystem considerations

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

1.3 Fishery description

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

1.4 Management History

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

1.5 Management performance

Yelloweye Rockfish removals have been substantially reduced since its designation as overfished in 2002 through a variety of management measures that eliminated retention in recreational fisheries, limited commercial retention, created broad spatial closures, and implemented new gear restrictions that reduced trawling in rocky habitats. Many of these restrictions remain in effect, though as Yelloweye Rockfish and other groundfish stocks have begun to rebuild, some management measures have been modified or removed in recent years. These include some additional allocations to recreational fisheries that remain constrained by Yelloweye Rockfish estimated discard mortality, the recent removal of the Yelloweye Rockfish Conservation Area (RCA) for the trawl sector off of California and Oregon, and eliminating some gear restrictions in the RCAs for the non-trawl sector.

Recent trends in total catch relative to management guidelines is available in Table 1 and shows that total catch of Yelloweye Rockfish has remained below both the OFL and ACL in each year since the previous assessment. Catch in Table 1 combines the two areas in this model as catch limits for Yelloweye Rockfish are managed as a single coastwide unit and includes both landings and estimated discard mortality. As in the previous assessment, total catches for each fleet in this update include both landings and estimated dead discard mortality.

1.6 Fisheries off Canada and Alaska

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

2 Data

A summary of available data by type and fleet used in the Yelloweye Rockfish assessment is available in Figure 1. Data that have changed from the previous 2017 assessment are summarized below. No new data sources were considered in this update assessment.

Removals:

- Post-2016 landings and discards were added for all three states for the commercial and recreational fleets.
- A new Oregon historical recreational catch reconstruction was incorporated, which covered 1979 - 2000.
- A new Washington historical recreational catch reconstruction was provided by Washington Department of Fish and Wildlife (WDFW) and included changes to data from 1990-2016.

Composition Data:

- Length and age composition data were added from 2017 - 2024 for all states for the commercial and recreational fleets.
- Length and age composition data were also extended for the WCGBTS and the IPHC Longline survey.
- Some length and age composition data from the 2017 assessment had minor errors in how sample numbers were calculated, ageing error assignment, and doubled age samples and thus needed to be fixed. See Section 2.1.2 below.

Indices of Abundance:

- Indices that were updated with more recent data and/or updated methodology include:
 - Oregon Onboard Observer (2001 - 2024)
 - Oregon Department of Fish and Wildlife Oregon Recreational Boat Survey (ORBS) Dockside (release only) (2004-2024)
 - WCGBTS (2003 - 2024)
 - IPHC Longline Survey (2002 - 2024)

Biological Data:

- Length-weight relationship parameters were updated to include all the recent (2017 - 2024) fishery-independent data.
- Ageing error matrices were unchanged but some Oregon recreation ages were assigned the wrong ageing error and were corrected based on ODFW recommendations.

2.1 Fishery-Dependent Data

Updated fishery-dependent data, including removals, length and age compositions, and indices of abundance, are detailed below.

2.1.1 Landings

A summary of total removals are provided in Table 2 and Figure 2.

Recent commercial landings (2017-2024) were obtained from [Pacific Fisheries Information Network \(PacFIN\)](#) for California, Oregon and Washington. For the period from 2016 through 2023, updated West Coast Groundfish Observer Program (West Coast Groundfish Observer Program (WCGOP)) discard estimates were added to PacFIN landings by adding the annual dead discard mortality rate for the commercial sector in the Groundfish Expanded Mortality Multi-Year (GEMM) recorded discards to obtain the total catch of Yelloweye Rockfish within commercial fleets.

Bycatch for the At-Sea Pacific Hake fleet (A-SHOP) was updated from 2017 through 2024.

Recreational removals from [Recreational Fishery Information Network \(RecFIN\)](#) were updated for California, Oregon and Washington from 2017 - 2024. RecFIN removals include an estimate of discard mortality and represent total estimated removals. The Oregon Department of Fish and Wildlife (ODFW) provided updated historical recreational removals for Oregon from 1979 through 2000(Whitman (2024)). The WDFW provided updated historical recreational removals (1967-1989) and Washington Department of Fish and Wildlife Ocean Sampling Program (OSP) estimates (1990-2001). The historical recreational removals for 1971, 1974, and 1979 were not available and were filled in as the average of the two preceding and two following years. Historical data were filtered to marine catch areas 1-4. For OSP catch estimates, data included marine catch areas 1-4, up to the Bonilla-Tatoosh line. WDFW also provided updated catch estimates for 2002-2004, which did not include discard mortality. To adjust for this, we multiplied the average mortality rate from the following five years (2005-2009) by the total discards to calculate total mortality for those years.

2.1.2 Fishery-Dependent Length and Age Compositions

Updated length composition data for commercial catches (trawl and non-trawl) were available from PacFIN (extracted April 4, 2025) and from WCGOP for all three states. These include the years 2017 - 2024 for PacFIN data and 2017 - 2023 for WCGOP data. Updated recreational length composition data were available from RecFIN (extracted April 4, 2025) for all three

states, and include years 2017 - 2024. Additionally, updated length compositions from the California On-Board CPFV Observer Sampling Program and from the Ocean Recreational Fishery Survey (ORFS, previously the Oregon onboard recreational observer program), both of which measure fish discarded at sea, were also available up through 2024 on RecFIN.

New commercial age composition data from PacFIN and WDGCOP for 2017-2024 was included for Oregon and Washington. No new commercial age data were available from California. New recreational age composition data was available from RecFIN from 2017 - 2024 for Washington only (extracted May 13, 2025). These data were collected in the OSP. There were also some historical updates to Oregon and Washington recreational age data provided by the state representatives.

In addition to extending the length data time series, we also fixed minor data errors found in the 2017 assessment. For length composition data, years with small samples sizes ($N = 1$) were excluded. There were no changes in how commercial length sample numbers were calculated. However, all recent recreational fleet length data were missing the total number of trips information used to calculate the number of samples. Using data from the 2017 assessment, we built fleet-specific linear regressions to approximate the relationship of samples to the number of fish. Then, we applied that regression to the total number of fish for data between 2017 and 2024 to estimate the number of samples. A future benchmark assessment should investigate how to get the number of sampled trips from RecFIN to calculate the number of samples using the I. J. Stewart and Hamel (2014) method.

We also found that conditional age-at-length (CAAL) data from the 2017 assessment had all sample sizes and relative proportions doubled, potentially from when Yelloweye Rockfish was changed from a two-sex to single-sex model. For most fleets this was not a problem because the proportions of age-at-length counts were the same, however, some of the commercial fleets included discard age proportions that were not doubled, leading to small differences in proportions. To fix the CAAL data so it accurately represented the number of fish in each age class, we either rebuilt the entire fleet's CAAL data frame using the most recently pulled information from PacFIN and RecFIN, or divided the number of samples or relative proportions in each length bin by two. How these problems were treated for each fleet specifically is detailed below, including other minor data changes. Otherwise, length and age composition data are unchanged from the previous assessment; please refer to the most recent benchmark assessment (Gertseva and Cope 2017) for additional information.

2.1.2.1 Fleet Specific Changes in the Compositional Data

Fleet 2. California Non-Trawl:

- For ages, all the CAAL and marginal ages (used to explore fits only, not included in the likelihood) data were recalculated using the most recent age data pulled from PacFIN and WCGOP, to account for age doubling in 2017.

Fleet 3. California Recreational:

- CAAL data for 1979-1984 were doubled, so the number of samples and age-at-length proportions were divided by two.
- CAAL data for 2009-2016 were doubled, but the raw data we received from RecFIN were correct, without doubled ages, so this time series was replaced with newly pulled data.
- We then re-built the marginal age data from the updated CAAL for both time periods because there were errors in previous data entry and sample number calculations.

Fleet 4. Oregon/Washington Trawl & Fleet 5. Oregon/Washington Non-Trawl:

- Both the OR/WA commercial fleets had all CAAL and marginal age (not included in the likelihood) data recalculated using the most recent age data pulled from PacFIN and WCGOP, to account for age doubling in 2017.

Fleet 6. Oregon Recreational:

- CAAL data sample sizes and proportions were doubled so numbers from 1979 - 2017 were divided by two.
- We included 2015 unsexed ages.
- We also reassigned the aging error for this fleet for the correct years. The ODFW data representative confirmed that all fish from 1979-2002 were aged by WDFW (ageing error 1), and fish from 2009-2016 were aged by the NWFSC (ageing error 2). No new ages since 2016 were provided. Marginal data were then recalculated from the updated CAAL so that the ageing error labels and number of samples matched.

Fleet 7. Washington Recreational:

- All age data from 1998 to 2024 were replaced with the most recent data provided in RecFIN, following the recommendation of the WDFW representative. CAAL and the marginal age data were calculated using this data.

2.1.3 Indices of Abundance

Two fishery-dependent indices of abundance were updated with new data and up-to-date methodology. These are detailed below. Otherwise, indices of abundances are unchanged from the previous assessment; please refer to the most recent benchmark assessment (Gertseva and Cope 2017) for additional information.

2.1.3.1 Oregon Onboard Observer CPUE, 2001 – 2024 -

The Oregon Onboard Observer (now Ocean Recreational Fisheries Survey, or ORFS) index was updated from the previous Yelloweye Rockfish assessment, and updated drift-level catch-per-unit-effort data was obtained from ODFW through the end of 2024. The database contains information on catch by species (number of retained and released fish), effort (angler hours), sample depth, and bag limits and other relevant regulations (Monk et al. 2013).

The unfiltered data set contained 18,410 drifts. Multiple standardized filters are applied to remove outliers and data unsuitable for an index. These filters are very similar to filters applied in 2017 and include drifts without data needed for CPUE information, long drifts (above 95th percentile), drifts in deeper waters (more than 64fm, 99th percentile), drifts that were targeting primarily mid-water species, and drifts outside of the legal fishing depth (with a five fm buffer). Additionally, years with extremely low sample sizes (<50) were excluded. Finally, drifts on charters from Port Orford were removed due to small sample sizes. The final filtered data set included 6,839 trips with a 6.1% encounter rate for Yelloweye Rockfish Table 3.

Covariates evaluated included year, month, port, the open depths to fishing (all depths or inside 20/30/40fm), and a five fm-binned depth of drift covariate. This is in contrast to the 2017 index, which was only able to evaluate a year covariate. The covariates listed above are standard to evaluate for this index in other assessments. Negative binomial models were fit using [Species Distribution Models with Template Model Builder](#) (sdmTMB) (version 0.6.0; Anderson et al. (2024)) to the drift-level data (catch with a log offset for adjusted angler hours). A model without the open fishing depths or month was selected as the best fit model by AIC Table 4. Acceptable diagnostics for the model were achieved, as evidenced by passing the sanity function in sdmTMB (Figure 3). The index of abundance is shown in Figure 4. A comparison to the ORFS index used in the previous assessment indicates that despite the change in modeling approach and the covariates included, most years overlap between the two indices and similar trends are observed Figure 5. The updated index has reduced within-year variance and a lack of extreme swings in the standardized index value (e.g. 2013) relative to the index from 2017.

2.1.3.2 Oregon ORBS Dockside (release only) CPUE, 2004-2024

The ORBS dockside index for Oregon was updated for this assessment. CPUE, expressed in terms of fish per angler-hour, was calculated by multiplying the number of anglers and the total trip time, minus the boat type-specific travel time. The database contains information on released fish by species (number of angler-reported released fish), effort (angler hours), sample location (port where data were collected), date, bag limits and other relevant regulations, boat type (charter or private), and trip type (e.g., bottom associated fish).

The unfiltered data set contained 504,128 trips from 2001 - 2024. Since the previous Yelloweye assessment, multiple data filters have been standardized, which are very similar to the 2017 assessment, and are applied to ORBS trip-level data to remove outliers and data unsuitable for an index. For this index, the time period was restricted to years when retention of Yelloweye Rockfish was prohibited, which began on January 1, 2004. There were two differences in the filtering in this updated index. First, the previous index began in 2005, which was determined to be an error in the timing of the implementation of prohibited status for Yelloweye. Given that prohibition was in effect on January 1, the year 2004 is included in this updated index. The second difference in filtering is the elimination of the Stephens-MacCall filter in the updated index. This filter has not been used for several assessment cycles, based on a recommendation from NWFSC staff (pers. comm. A. Whitman, ODFW). The final dataset included 133,039 trips from 2004 – 2024 with an overall encounter rate of 7.4% Table 5.

Covariates evaluated included year, month, port, the open depths to fishing (all depths or inside 20/30/40 fm), and boat type. These are the same covariates evaluated in the 2017 ORBS index, apart from the open depths of the fishery. The final model in 2017 included boat type, port and year. Negative binomial models were fit in `sdmTMB` (Version 0.6.0) to the trip-level data (catch with a log offset for adjusted angler hours). The final model selected includes year, month, port, boat type and open fishery depths, which was the best fit model by AIC in this series Table 6. Acceptable diagnostics for the model were achieved, as evidenced by passing the sanity function in `sdmTMB`. (Figure 6). The index of abundance is shown in Figure 7. ODFW no longer maintains the `deltaGLM` code that was used to develop the 2017 index and so the index was updated to use the currently accepted modeling approach for Pacific Fishery Management Council (PFMC) groundfish assessments (`sdmTMB`, version 0.6.0; Anderson et al. (2024)). To bridge this change, the 2017 model index structure was applied to the current dataset using `sdmTMB` and compared to the `deltaGLM` index used in the 2017 assessment and the current recommended updated index in Figure 8. There are some differences observed in 2005 – 2009 between the `deltaGLM` index and the two `sdmTMB` indices; however, this appears to be largely driven by the updated modeling approach.

2.2 Fishery-Independent Data

Two sources of fishery-independent data were updated: the West Coast Groundfish Bottom Trawl Survey and the IPHC Longline survey.

2.2.1 West Coast Bottom Trawl Survey (WCGBTs)

The WCGBTs survey methods are most recently described in detail in Keller, Wallace, and Methot (2017). Geostatistical models of biomass density were fit to survey data from the WCGBTs using [Template Model Builder \(TMB\)](#) (Kristensen et al. 2016) via the `sdmTMB` R

package (Anderson et al. 2024) as configured within the [indexwc](#) R package (Johnson et al. 2025). These models can account for latent spatial factors with a constant spatial Gaussian random field and spatiotemporal deviations to evolve as a random walk Gaussian random field (Thorson et al. 2015). Delta-gamma and delta-lognormal distributions were investigated. Results are only shown for the model that led to the best model diagnostics, defined as similar distributions of theoretical normal quantiles and model quantiles (Figure 9), high precision, lack of extreme predictions, and low Akaike information criterion (AIC). Estimates of biomass from this best model were predicted using a grid based on available survey locations.

The final model used a delta model with a lognormal distribution for the catch-rate component. A logit-link was used for encounter probability and a log-link for positive catch rates. The response variable was catch (mt) with an offset of area swept (km^2) to account for differences in effort. Fixed effects were estimated for each year and pass. The index was estimated for the area north of 4210 (Oregon and Washington) to be consistent with the previous assessment. The data were truncated to depths shallower than 325 m prior to modeling given that there were zero positive encounters in depths deeper than 325 m. The prediction grid was also truncated to only include available survey locations in depths between 55–325 m to limit extrapolating beyond the data and edge effects. Spatial variation was included in the encounter probability and the positive catch rate model. Spatial variation was approximated using 200 knots, where more knots led to non-estimable standard errors because the positive encounters are too sparse to support the dense spatiotemporal structure. Anisotropy was not estimated.

The biomass estimates produced for this assessment using `sdmTMB` are comparable to the biomass estimates produced in the previous benchmark assessment (Figure 10). The index is relatively flat with a peak in 2014, but variation is high throughout the time series (Figure 11).

2.2.2 IPHC Setline Survey

The IPHC has conducted an annual longline survey for Pacific halibut off the coast of Oregon and Washington (IPHC area “2A”) since 1997 (no surveys were performed in 1998 or 2000). Beginning in 1999, this has been a fixed station design, with roughly 1,800 hooks deployed at each of 84 locations. Before 1999, station locations were not fixed, and, therefore, those years are not used in the index. Rockfish bycatch, mainly yelloweye, was recorded during this survey, although values for 1999 and 2001 are estimates based on subsampling the first 20 hooks of each 100-hook skate. The gear used to conduct this survey, while designed specifically to efficiently sample Pacific halibut, is similar to that used in some earlier line fisheries that targeted adult Yelloweye Rockfish. Some variability in exact sampling location is unavoidable, and leeway is given in the IPHC methods to center the set on the target coordinates but to allow wind and currents to dictate the actual direction in which the gear is deployed. This can result in different habitats accessed at each fixed location among years. The number

of skates used can also differ from year to year; skates hauled (i.e., 100 hooks/skate) are thus used as the unit of effort for all years. This has been the standard effort used in past Yelloweye Rockfish stock assessments.

New to this assessment is the consideration of eight additional survey stations (1527 to 1534) conducted in a collaborative effort between IPHC and WDFW from 2007-2009, 2013-2019 and 2021-2023. These stations are arranged around IPHC station 1082 (one of the more notable stations to encounter Yelloweye Rockfish). Only the summer months are considered here to match the time of year sampled by the IPHC survey. Survey sets at the WDFW stations used three skates with 100 hooks each for most years, except for 2021 - 2023, where a total of four skates were used. Like the IPHC survey, effort was standardized to 100 hooks/skate. These stations were integrated into the IPHC stations when calculating the index of abundance. The full survey used in this assessment combined all stations in Oregon and Washington into a single index. Data were first filtered to remove all depths with few or no encounters, and then we excluded stations that rarely encountered Yelloweye Rockfish (averaging less than one encounter a year). This left a total of 11 stations for analysis. Both filtering levels increased the percentage of encounters from an initial 11% to 80%.

A log-normal generalized linear model with a log link in the `sdmTMB` R package (Anderson et al. 2024) was used to standardize the CPUE. Model selection using the Akaike Information Criteria for small samples (AICc) was conducted to select which variables were included in the model. The final model included year, station, and depth as explanatory variables. Diagnostic tools to ensure the model fit was satisfactory included checking whether the hessian matrix is positive definite, the presence of extreme eigenvalues, and if the non-linear minimizer suggests convergence. These diagnostics were conducted with the `sanity` function in the `sdmTMB` package. The updated index is compared to the index used in 2017 in Figure 13.

2.2.3 Fishery-Independent Length and Age Compositions

Updated length and age composition data were available for the two updated fishery-independent surveys. Compositional data from 2017 through 2024 were updated for WCGBTS were obtained using functions from the `indexwc` R package (Johnson et al. 2025). The IPHC survey compositional data were provided by WDFW.

A summary of sampling efforts (number of hauls and number of individual fish) in all surveys is provided in Table 7 and Table 8. Updated year-specific length frequency distributions generated for each survey are shown in Figure 14 and Figure 15, respectively. Updated year-specific CAAL frequencies for each survey are shown in Figure 16 and Figure 17 for the WCGBTS and Figure 18 and Figure 19.

2.3 Biological Parameters and Data

The approach to natural mortality, maturity and fecundity were unchanged from the previous assessment (Gertseva and Cope 2017). All of these biological parameters used in the assessment were estimated outside the model or obtained from literature. Therefore, uncertainty reported for the stock assessment results does not include any uncertainty in these quantities (however, some were investigated via sensitivity analyses described later in this report). The parameters for the length-weight relationship were updated to include the most recent data from 2017 - 2024; see the updated equation: $W = 7.18331 \times 10^6 L^{3.2448}$ (Figure 20). Aging error matrices were unchanged.

3 Assessment model

3.1 History of modeling approaches

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

3.2 Responses to SSC Groundfish Subcommittee requests

To be completed after SSC GFSC review.

3.3 Model Structure and Assumptions

3.3.1 Description of New Modeling Approaches

This section is not required for an update assessment.

3.3.2 Modeling Platform and Structure

The assessment was updated to use the most recent version of Stock Synthesis 3 (Version 3.30.23.2 - available [online](#)). Bridging between SS versions is discussed in Section Section 3.3.3.

Briefly, the Yelloweye Rockfish model is a coastwide, single-sex, two-area model. California is Area 1, and Oregon and Washington are combined into Area 2; the areas are separated because of differences in potential exploitation rates by area over time. Yelloweye Rockfish compositional data are primarily reported as both sexes combined, and therefore, the previous assessment used a single sex model to facilitate the use of all available data. Growth is assumed to be the same in both areas, though future benchmark assessments may want to re-evaluate this assumption if more spatially-explicit data become available. Both growth and initial recruitment parameters were estimated internally, while all other biological parameters were fixed. The modeling period starts in the first year of available catches from historical reconstructions (1889) and the stock is assumed to be at an unfished equilibrium prior to that time. No changes were made to the fleet structure of the model. Fishery removals were divided among seven area- and sector-specific fleets. Estimated discard mortality was added to landings and included in the model as fleet-specific total removals. Length compositions

for discarded and retained fish were combined as well. Data weighting was done using the Francis method (Francis 2011) but the McAllister-Ianelli method was explored as a sensitivity. More detailed information on the model structure and justification is available in Gertseva and Cope (2017) and summarized in [?@tbl-table_config](#).

3.3.3 Model Changes from the Last Assessment

A list of changes that were made to the model compared to the previous assessment (Gertseva and Cope 2017) are listed below.

- Data:
 - Detailed information on specific updates and changes to the data included in the model are included in Section [Section 2](#) but are summarized below.
 - The landing time series were corrected and updated through the end of 2024 for California, Oregon and Washington. Overall, there was little change in the model results when updating and extending the catch time series, even after changes in the historical catch ([?@fig-bridge3-comp2](#) and [?@fig-bridge3-comp4](#)). Though, the age 8+ biomass increased more for the most recent years than the forecasted estimates from 2017 ([?@fig-bridge3-comp18](#)).
 - Indices of abundance were updated with recent data, where available, and re-analyzed using more up-to-date methods. Updating indices lead to a slight decrease in $\ln(R_0)$, reducing the spawning output by very little ([?@fig-bridge5-comp2](#)).
 - Length and age compositions from all fishery removal and index fleets were updated and tuned through 2024. The addition of composition data greatly increased $\ln(R_0)$, which led to an increase in the spawning output, particularly for 1920-1980 ([?@fig-bridge14-comp2](#)). This new data also changed the pattern of the recruitment deviations significantly from 1990-2024 ([?@fig-bridge14-comp11](#)). From 1990-2005 recruitment was lower than predicted in the last assessment, then from 2006-2016 recruitment was higher than the past, and finally recruitment dropped very low for 2017-2021. This shift to lower estimated recruitment for recent years seems to have slowed the recovery curve ([?@fig-bridge14-comp2](#)).
- Fleet structure:
 - No changes were made to the fleet structure.
- Biology:
 - No changes were made to the biological parameterization of the model; however, the length-weight relationship was updated to include the most recent data from the WCGBTS and did not change the model fit. The impact of updating the length-weight relationship is evaluated as a sensitivity.

- Recruitment:
 - The control file settings for the bias adjustment were updated to improve the fit of the bias adjustment relationship for recruitment deviations (Methot and Taylor (2011)).
- Selectivity and retention:
 - The end year for all time blocks was extended to 2024.
 - All final updates in the control, starter, and forecast files showed little to no additional change in the model (**Figure XXX need to make figure that just shows change from tuned to new base**).
- Software and Workflow
 - Updating to SS3 3.30.23.2 and to the most recent version of the SS3 executable had no discernable impact on model results (Figure 21).
 - Use most up-to-date R packages to process input and output files for the assessment, including *nwfscDiag*, *r4ss*, and *pacfintools*.
 - Created a public github repository for Yelloweye Rockfish (“sebastes_ruberrimus_2025”) to provide a transparent and reproducible system for processing the data and creating the model and assessment document [online]https://github.com/rclairer/Sebastes_ruberrimus_2025.

3.3.4 Key Assumptions and Structural Choices

This section is not required for an update assessment; please refer to the most recent full assessment (Gertseva and Cope 2017) for additional information.

3.3.5 Priors

The natural mortality prior standard deviation was updated to be consistent with methods described in Hamel (2015).

3.3.6 Data Weighting

Length data from the WGBTS and fishery discards, conditional age-at-length compositions from the WGBTS, and marginal age compositions from the fishery fleets and other surveys were fit and appropriately weighted using an iterative approach. The Francis method (Francis (2011)) was used twice with two iterations to tune the length and age data simultaneously

(Table 12). For conditional-age-at-length data, it was assumed that each age was a random sample within the length bin, and thus, the model started with a sample size equal to the number of fish in that length bin. A sensitivity is included to examine differences in parameter estimates when data weighting was implemented using the McAllister–Ianelli method (McAllister and Ianelli (1997)), which is based on the harmonic mean.

Additional variance was estimated and added to the input variance for all indices with the exception of the WCGBTS.

3.3.7 Model Parameters

The base model had 188 estimated parameters (tallied by type in [?@tbl-table_parcounts](#)). A single-sex growth curve was estimated (Figure 28). Natural mortality was fixed, as in the 2017 assessment. Unfished recruitment and the distribution of recruits between areas are estimated. Steepness of the stock-recruit relationship was kept fixed at 0.718, matching the 2017 assessment. Estimating steepness was evaluated as a sensitivity. Recruitment deviations during the “main” period (from 1980 to 2023) were forced to sum to zero and the bias adjustment ramp was updated (Figure 29).

All selectivity was assumed to be length-based and used a double-normal functional form. Selectivities for all fleets was estimated to be asymptotic (Figure 30), though selectivity for the California Onboard Observer CPUE was mirrored to the California recreational fleet. Selectivity was constant through time. Dome-shaped selectivity and various time blocks for specific fleets were explored in Gertseva and Cope (2017) but not re-evaluated in this update assessment.

Aging error matrices were estimated outside the assessment model and were unchanged from the previous assessment, with the exception of designating the correct error matrix in some years for the Oregon recreational ages.

3.4 Base Model Results

We havent updated this section yet since Kiva looked at it, we definitely need more time for this section and to cut out the fluff

3.4.1 Parameter Estimates

The list of the all the parameters used in the assessment model and their values (either fixed or estimated) is provided in Table 11. The growth parameters estimated within the model are

reasonable, commensurate with inspection of the raw data and consistent with what we know about the species, a long-lived rockfish with relatively slow growth and large asymptotic sizes. These parameters are relatively precisely estimated in terms of the asymptotic standard error estimates. Figure 28 shows the estimated growth curve. Spawning output-at-length is shown in Figure 31. Spawning output in the assessment is expressed in millions of eggs.

Estimated stock-recruit function for the assessment model is shown in [?@fig-SR_curve](#). Estimated recruitment deviations are shown Figure 33. Recruitment of Yelloweye Rockfish was estimated to be quite variable over time, with the most recent years experiencing slightly lower than average recruitment after periods of low and high recruitment during the late 1980s to the early 200s, and late 2000s to late 2010s, respectively. Reflecting these variable recruitment patterns, the estimated stock-recruit function predicts a relatively wide range of cohort sizes over the observed range of spawning biomass. The model output recruitment variance ($RMSE = 0.48$) is consistent with the fixed input recruitment variance ($R = 0.5$).

Length-based selectivity curves estimated in the assessment are shown for all fleets together in Figure 30. Estimated selectivity curves for the fishing fleets indicate that the recreational fleets access somewhat smaller fish than the commercial fisheries. This pattern is most pronounced in Oregon, and also as expected, since recent charter fishing selectivity has shifted shoreward where there is a higher density of smaller fish. Addition of the charter vessel length data did not appreciably change the estimate for the California recreational selectivity pattern and so the selectivity for the two series was not separated. All fleets for which curves were allowed to be dome-shaped (commercial trawl and non-trawl fleets) were estimated to be asymptotic. Estimated selectivity curves for the IPHC survey indicate a selection of the largest Yelloweye available, and select the least amount of smaller Yelloweye Rockfish (Figure 34). The NWFSC trawl survey selected far more smaller Yelloweye among all surveys (Figure 35). That the triennial survey selectivity was shifted to the largest fish but also selected some very small fish is likely an artifact of the very noisy composition data from that survey (Figure 36).

3.4.2 Fits to the Data

Model fits to the fishery CPUE and survey indices are presented in Figure 37 through Figure 44. The base model predicted a decreasing trend in the triennial survey between 1980 and 2004 (Figure 42) and a slightly increasing trend for the NWFSC trawl survey between 2003 and 2024 (Figure 43). The model predicted a relatively flat trend through the IPHC survey index despite the upward trend seen in the last three years as of this update (Figure 44). The triennial survey index indicated a population decrease in 1992 and lower estimates (compared with pre-1992) persisted through the end of the index time series. This decrease in the abundance index coincided with decrease in number of biological samples collected from this survey. No changes have been implemented to the triennial survey between 1989 and 1992. In 1995, the survey timing slightly shifted from early fall to mid-summer, approximately a month

earlier than previous surveys. This shift in timing, however, seems unlikely to impact our understanding of Yelloweye Rockfish abundance trends during that period, given the sedentary life history of the species. Additionally, the change in the index trend was observed before the slight shift in survey timing. The California Marine Recreational Fisheries Statistics Survey (MRFSS) recreational CPUE index tracked the decline in observations through the 1990s (Figure 37), and a slight increase in abundance was predicted in the Oregon MRFSS/ORBS recreational index during the 2000s (Figure 38). The Oregon recreational observer index showed a small and very uncertain increasing trend in the 2000s (Figure 41). The California commercial passenger fishing vessel (CPFV) charter series index indicated a relatively flat trajectory prior to 1992 with a drop in stock abundance from 1992 on (Figure 40). The model predicted a decreasing trend for the Washington Recreational index despite the relatively large variances on many of the observations, which does not match the relative stability of the index from 1982 to the early 2000s (Figure 39).

The model fitted length data aggregated across years reasonably well for all fleets (Figure 45). Pearson residuals for the fits by fleet and year are shown in Figure 46 and Figure 47. The length data are very sparse in many years and the quality of fit varies among years and fleets, reflecting the differences in the quantity and quality of the data. However, neither length composition data nor the Pearson residuals, which reflect the noise in the data both within and among years, exhibit obvious patterns for any fleet. The data for fishing fleets are particularly poor after 2002 after retention of Yelloweye Rockfish was prohibited in most fleets and limited in trawl fleets. Input sample sizes for length composition data were tuned down using the Francis data weighting method (Table 12).

3.4.3 Population Trajectory

The estimated time series of spawning output for the entire stock and by area are shown in Figure 48 and Figure 49, respectively. Spawning output relative to SB0 for the entire stock and by area are shown in **?@fig-status_combined** and **?@fig-status_area**. Total biomass, summary biomass and recruitment are shown in Figure 50, Figure 51 and Figure 52, respectively. Trends in total and summary biomass, absolute and relative spawning output track one another very closely. The spawning output of Yelloweye Rockfish started to decline in the 1940s during World War II, but are estimated to have been lightly exploited until the mid-1970s when catches increased and a rapid decline in biomass and spawning output began. The combined relative spawning output reached a minimum of 16% of unexploited levels in 2000 (Figure 48). Yelloweye Rockfish spawning output and relative status is estimated to have been gradually increasing since that time, in response to large reductions in harvest. However, the aggregate spawning output estimates do not convey the spatial heterogeneity included via the area-specific dynamics. Relative spawning output has differed between the two areas modelled in the assessment, with the California resource estimated to have a lower unfished equilibrium spawning output and estimated to be more depleted in 2025 than the Oregon and Washington resource (**?@fig-status_area**).

Recruitment appears to be relatively dynamic over time, with several elevated peaks over time estimated in the age-0 recruits (Figure 52). An initial peak in the mid-1940s is followed by two periods of elevated recruitment in the 1970s and early 1980s and another period centered around the 2010s. This trend is consistent with the previous assessment, apart from the most recent elevated time period, which estimated a sole peak in 2001 and several other peaks of smaller magnitude starting in 2005. Recruits for this assessment appear to have extended and increased this more recent time period starting in 2005, with a peak in 2008 and 2013 and shifts the peak in 2001 to 2002. Recruitment in the late 2010s was estimated to be lower, but a more recent increase is seen starting in 2020.

3.5 Model Diagnostics

3.5.1 Convergence

Model convergence was evaluated by starting the minimization process from dispersed values of the maximum likelihood estimates to determine if the model found a better minimum. Starting parameters were jittered using the jitter function built into Stock Synthesis, using a jitter input of 0.10. This was repeated 50 times with 78% of runs returning to the base model likelihood. A better, lower negative log-likelihood, model fit was not found. The spread of this search indicates that the jitter was sufficient to search a large portion of the likelihood surface, and that the base model is at a global minimum (Figure 53). Through the jittering and the likelihood profiles, we are confident that the base model, as presented, represents the best fit to the data given the assumptions made. There were no difficulties in inverting the Hessian to obtain estimates of variability. The final gradient was 0.00087.

3.5.2 Sensitivity Analyses

3.5.2.1 Sensitivity to assumptions about model structure

Sensitivity analyses to examine the impact of different assumptions about model structure on management quantities included a model with an estimated natural mortality rate (M), one with estimated steepness (h) of the stock-recruit relationship, and one using the 2017 length-weight relationship. Summaries of model results for these sensitivities are presented in **?@tbl-sens-mod-results**.

The estimated natural mortality was slightly higher than that of the base model (~ 0.053 compared to ~ 0.044 from the base model). Steepness was estimated much higher at 0.905, similar to what the 2017 assessment estimated, which would otherwise indicate recruitment is less dependent on the spawning stock biomass, especially at small stock sizes. However,

steepness values close to 1 are implausible for slow growing rockfish, supporting the decision to fix steepness at 0.718.

Model results are sensitive to whether natural mortality and steepness are estimated or fixed, with the alternative models estimating a higher spawning output and a lower depletion status when compared to the base mode (Figure 54 and Figure 55). However, outputs of the model using the 2017 length-weight relationship showed the base model is not sensitive to this update, with very similar spawning outputs between the base and alternative model (Figure 54 to Figure 55).

3.5.2.2 Sensitivity to data set choice and weighting schemes

Sensitivity analyses to data set choices to examine the impact of including different data streams were conducted by selectively removing each data source using emphasis factors, as well as by including different weighting schemes for composition data. Summaries of model results for these sensitivities are presented in Table 14 and Table 15. Among these, the base model appears to be most sensitive to removing length compositions, which show a significantly different biomass trajectory and a more optimistic estimate of stock status at the end of the time series (Figure 56 and Figure 57). Removing all age compositions, IPHC age compositions only, and applying the McAllister & Ianelli weighting scheme also result in slightly more optimistic estimates of stock status at the end of the time series compared to the base model (Figure 56 and Figure 57). Furthermore, models with all abundance and IPHC indices removed resulted in slightly less optimistic estimates of spawning output and stock status at the end of the time series (Figure 58 and Figure 59). Models removing the remaining indices consecutively did not show large differences in the final stock status estimate. A summary of the relative changes in management quantities from all sensitivity models is shown in Figure 60.

3.5.3 Retrospective Analysis

A retrospective analysis was conducted by running the base model with data removed for the past 5 years. Comparisons of the time series of absolute and relative spawning output and recruitment deviations time series for the runs are shown in Figure 61, Figure 62, and Figure 63, respectively. Recruitment deviations were more positive as years were removed. However, the change is not large, indicating that the new data are consistent with previous values or the sample sizes are too small to have any impact.

General trends in relative depletion (or spawning output) have been relatively stable across assessments (Figure 64), with a decline throughout the later half of the 1900's as the stock was fished down, followed by a reversal in the overall status after substantial catch restrictions were

implemented in 2002. Across the most recent assessments, the 2017 assessment (Gertseva and Cope 2017) appears to have the most pessimistic depletion across the stock decline in the 1900s but otherwise, the relative depletion trend appears to be similar across the 2011, 2017 and the 2025 assessment as the stock has rebounded from its lowest status.

3.5.4 Likelihood Profiles

Likelihood profiles were conducted for natural mortality (M), stock-recruit steepness (h), and equilibrium recruitment ($\ln R_0$). These likelihood profiles were conducted by fixing the parameter of interest at specific values and estimating the remaining parameters based on the fixed parameter value.

In the assessment, M was fixed at the value of 0.044, based on Hamel's prior. The profile analysis over M showed that the negative log-likelihood was minimized with a value around 0.052 (Figure 65), which is close to what was assumed in the assessment. The time series of absolute and relative spawning output associated with different values of M ranging from 0.03 to 0.06 are shown in Figure 66.

In the base model h is fixed at 0.718, like the 2017 assessment, because much higher values (e.g. 0.9) are implausible given the life-history of slow growing rockfish. The likelihood profile for h shows that the negative log-likelihood for the base model declines with increasing h to a value around 0.7, notably different from the sensitivity analysis (Figure 67). Time series of relative unfished biomass associated with different values of h ranging from 0.25 to 1.0 are shown in Figure 68.

A likelihood profile analysis for $\ln(R_0)$ shows a strongly informed initial recruitment value in the base model (Figure 69). Most of the information for this parameter is coming from the length data. Within the length composition likelihood component, all sources of length compositions are equally informative. The index and age data are relatively uninformative. Changes in $\ln(R_0)$ results in relatively small changes in the scale of the population (Figure 70 and Figure 71) compared to the 2017 assessment model.

3.6 Unresolved Problems and Major Uncertainties

4 Management

4.1 Reference Points

This assessment estimates that the stock of Yelloweye Rockfish off the continental U.S. Pacific Coast is currently at 35.7% of its unexploited level. This is above the overfished threshold of SB25%, but below the management target of SB40% of unfished spawning biomass. Both areas are above the overfished level of 25%. The assessment estimates that the coastwide spawning output of Yelloweye Rockfish dropped below the SB40% target for the first time in 1986 and below the overfished SB25% threshold in 1993, as a result of intense fishing by commercial and recreational fleets. It continued to decline and reached 14.2% of its unfished output in 2000 (Table 13). The same year, the stock was declared overfished. Since then, the spawning output has slowly increased due to management regulations implemented to foster stock rebuilding.

Reference points for the base model are summarized in Table 16. Unfished spawning stock output for Yelloweye Rockfish was estimated to be 1129.7 million eggs (95% confidence interval: 999.2-1267.2 million eggs). The stock is declared overfished if the current spawning output is estimated to be below the minimum stock size threshold (MSST) of 25% of unfished level (SB25%). The management target for Yelloweye Rockfish is defined as 40% of the unfished spawning output (SB40%), which is estimated by the model to be 452 million eggs (95% confidence interval: 397-507), which corresponds to an exploitation rate of 0.025. This harvest rate provides an equilibrium yield of 115 mt at SB40% (95% confidence interval: 101-130 mt). The model estimate of maximum sustainable yield (MSY) is 121 mt (95% confidence interval: 106-136 mt). The estimated spawning stock output at MSY is 327 million eggs (95% confidence interval: 287-367 million eggs). The exploitation rate corresponding to the estimated SPRMSY of F36% is 0.036.

This assessment estimates that the 2024 SPR is 0.221. **The SPR used for setting the OFL is 50%, while the SPR-based management fishing mortality target specified in the current rebuilding plan and used to determine the ACL is 76%.** Relative exploitation rates (calculated as catch/biomass of age-8 and older fish) are estimated to have been below 1% during the last decade. This assessment estimates that Yelloweye Rockfish was fished beyond the relative SPR ratio (calculated as 1-SPR/1-SPRTarget=0.5) between 1977 and 2000. The equilibrium yield curve is shown in Figure 72.

4.2 Harvest Projections and Decision Tables

The base model estimate for 2025 spawning depletion is 37.8%. The primary axis of uncertainty about this estimate used in the decision table was based on natural mortality.

Natural mortality in the assessment model is fixed at the median of the Hamel prior (0.044 y-1), estimated using the maximum age of 123 years. Natural mortality value for high state of nature was calculated to correspond to 97 years of age, which is the 99th percentile of the age data available for the assessment; this value was 0.056 y-1. The natural mortality value for low state of nature was calculated to correspond to 147 years of age, which is the maximum age reported for the Yelloweye Rockfish; this value was 0.037 y-1.

Twelve-year forecasts for each state of nature were calculated for two catch scenarios (Table 18). One scenario assumes 2025-2026 catches to be 60% of year-specific ACL values, and 2027-2036 catches to be 60% of removals calculated using current rebuilding SPR of 76% applied to the base model. The second catch scenario assumes 2025-2026 removals to be equal to year-specific ACLs, and 2027-2036 catches calculated using current rebuilding SPR of 76% applied to the base model.

4.3 Evaluation of Scientific Uncertainty

The model estimated uncertainty around the 2025 spawning biomass for the model is $\sigma = 0.026$. The uncertainty around the OFL in 2025 is $\sigma = 10.82$. Each of these are likely underestimates of overall uncertainty due to the necessity to fix several key population dynamics parameters (e.g., steepness, recruitment variance) and also because there is no explicit incorporation of model structural uncertainty (although see the decision table for alternative states of nature).

4.4 Regional management considerations

Yelloweye Rockfish is modeled in two areas (California and Oregon-Washington) in this assessment. Current population status does differ by area and may be valuable information for making management and allocation decisions (Figure 73).

4.5 Research and Data Needs

Please refer to the 2017 benchmark assessment for a detailed list of research and data needs for Yelloweye Rockfish (Gertseva and Cope (2017)). In addition to those, the following research and recommendations could improve the ability of future stock assessments to determine the status and productivity of the Yelloweye Rockfish population:

- Continue refining the ORFS index analysis and ultimately use either the ORBS or ORFS index to describe the CPUE trends in the Oregon recreational fishery after 2000.

- Expand the IPHC age composition bins to an older maximum age for the IPHC age composition data to spread out the distribution of length data in the oldest age bins for conditional age-at-length.

5 Tables

5.1 Introduction

Table 1: Recent trend in the overfishing limits (OFL), the acceptable biological catches (ABCs), the annual catch limits (ACLs), and the total dead catch (landings + discards) all in metric tons (mt).

Year	OFL (mt)	ABC (mt)	ACL (mt)	Total dead catch (mt)
2015	52	43	18	12
2016	52	43	19	9
2017	57	47	20	20
2018	58	48	20	19
2019	82	74	48	24
2020	84	77	49	18
2021	97	83	50	21
2022	NA	NA	NA	34
2023	90	75	52	39
2024	91	76	53	15

5.2 Data

Table 2: Time series of yelloweye rockfish catches by fleet used in the assessment. The fleets include yelloweye bycatch in foreign POP and in at-sea fisheries. Years 1967 - 1974, 1979, and 2002 - 2004 do not include catch in MT as that information is not available.

Year	CA trawl (mt)	CA non-trawl (mt)	CA sport (mt)	OR-WA trawl (mt)	OR-WA non-trawl (mt)	OR sport (mt)

5.3 Model results

Table 9: Specifications and structure of the model.

Section	Configuration
Maximum age	100
Sexes	Sexes combined
Population bins	8-88 cm by 2 cm bins
Summary biomass (mt) age	8+
Number of areas	2
Number of seasons	1
Number of growth patterns	1
Start year	1889
End year	2024
Data length bins	10-74 cm by 2 cm bins
Data age bins	0-65 by 1 year

Table 10: Estimated parameters in the model.

Type	Count
Growth mean	3
Growth variability	2
Stock-recruit	1
Rec. dev. time series	136
Rec. dev. forecast	12
Index	7
Index time-variation	1
Size selectivity	25

Table 11: Parameter estimates, estimation phase, parameter bounds, estimation status, estimated standard deviation (SD), prior information [distribution(mean, SD)] used in the base model.

Table 12: Data weightings applied to compositions according to the **Francis** method.

Obs. refers to the number of unique composition vectors included in the likelihood. **N input** and **N adj.** refer to the sample sizes of those vectors before and after being adjusted by the weights. **CAAL** is conditional age-at-length data.

Type	Fleet	Francis	Obs.	Mean N input	Mean N adj.	Sum N adj.
Length	1_CA_TWL	0.521	38	9.9	5.2	196.8

2033	—	—	—	120	0.824	99	99	533
2034	—	—	—	120	0.817	98	98	537
2035	—	—	—	120	0.809	97	97	540
2036	—	—	—	121	0.801	97	97	542

Table 18: TODO: UPDATE PLACEHOLDER DECISION TABLE CAPTION COPIED FROM PETRALE SOLE. Decision table with 10-year projections. ‘Mgmt’ refers to the three management scenarios (A) the default harvest control rule $P = 0.45$, (B) harvest control rule with a lower $P = 0.40$. In each case the 2023 and 2024 catches are fixed at the ACLs which have been set for that year with estimated fleet allocation provided by the GMT. The alternative states of nature (‘Low’, ‘Base’, and ‘High’ as discussed in the text) are provided in the columns, with Spawning Output (‘Spawn’, in trillions of eggs) and Fraction of unfished spawning output (‘Frac’) provided for each state.

Mgmt	Year	Catch	Low Spawn	Low Frac	Base Spawn	Base Frac	High Spawn	High Frac

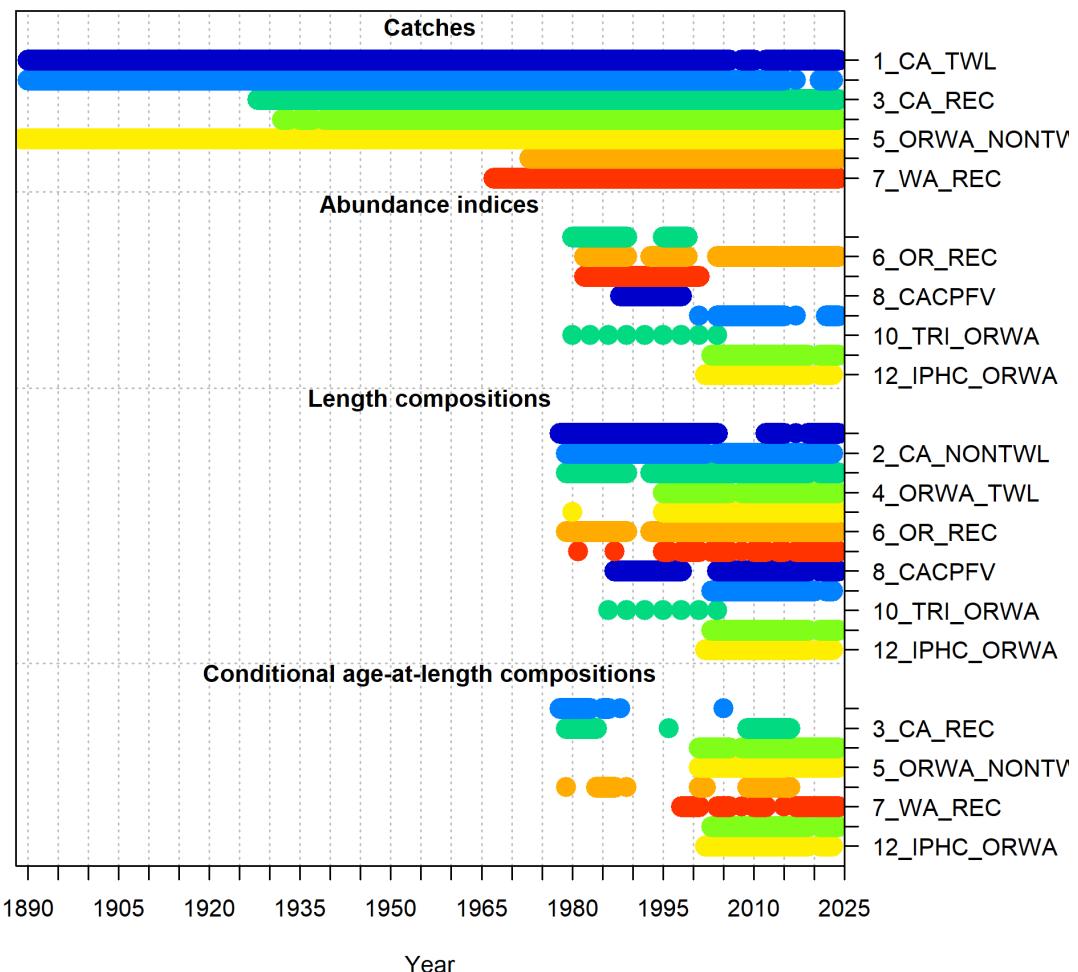

Figure 1: Summary of data sources used in the base model.

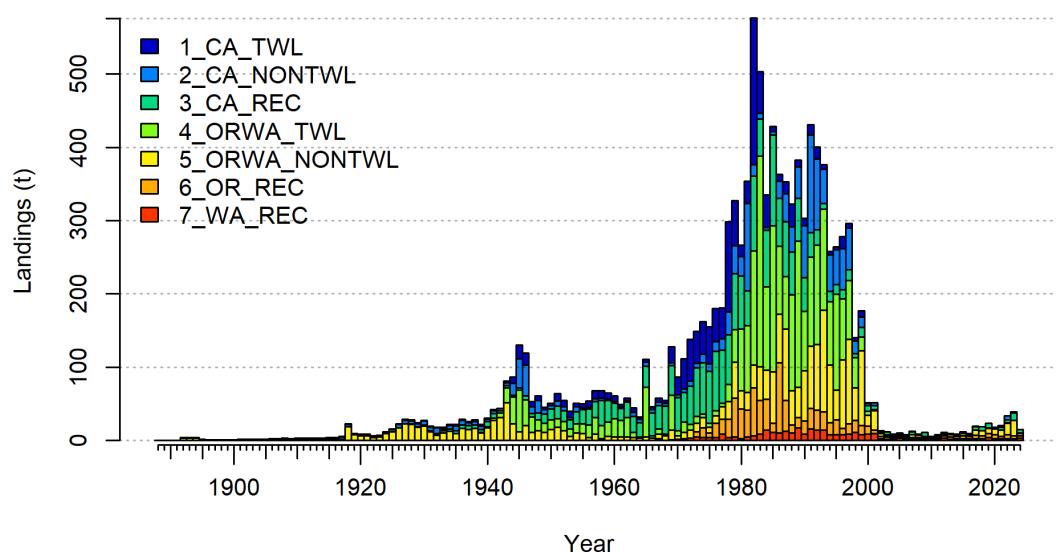

Figure 2: Landings (mt) by year and fleet.

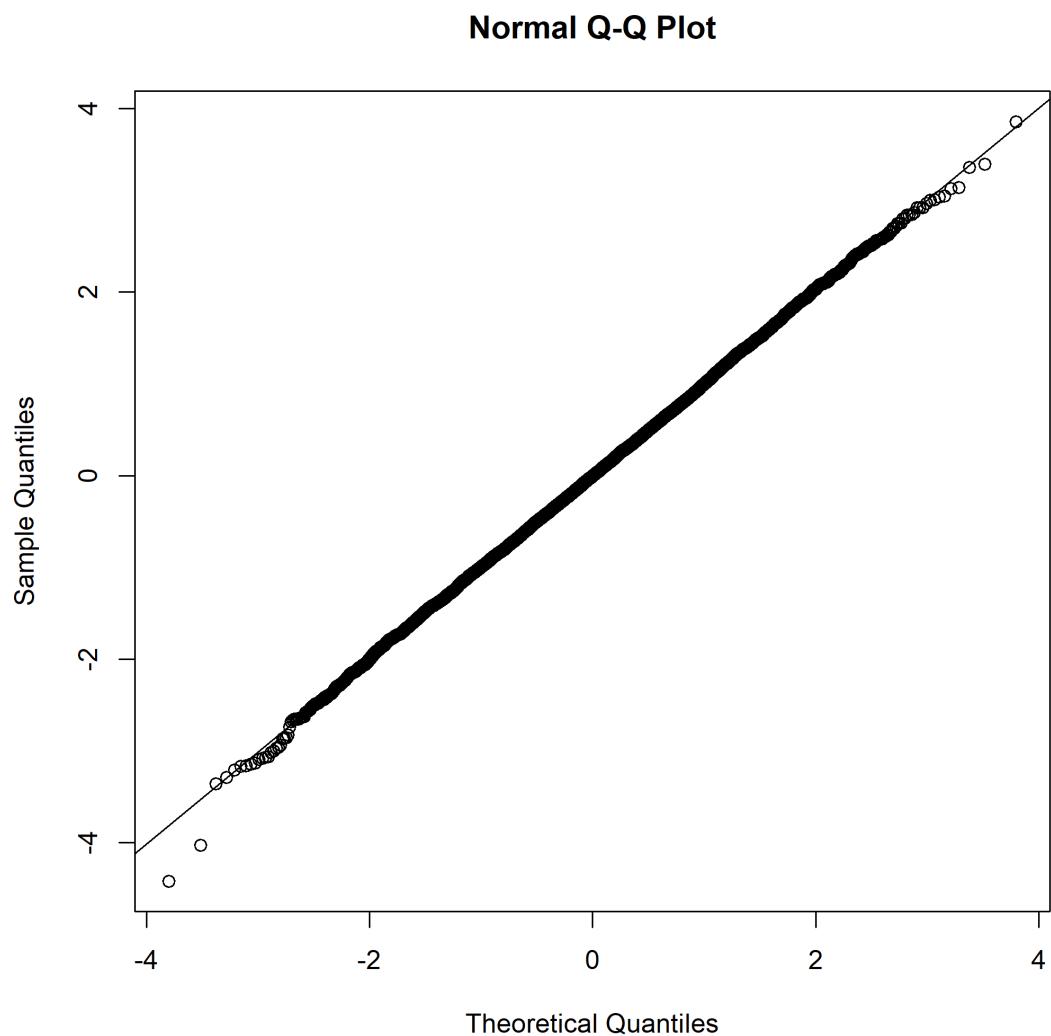

Figure 3: Quantile-quantile plot for the sdmTMB model fit for the Oregon Onboard Observer (ORFS) index.

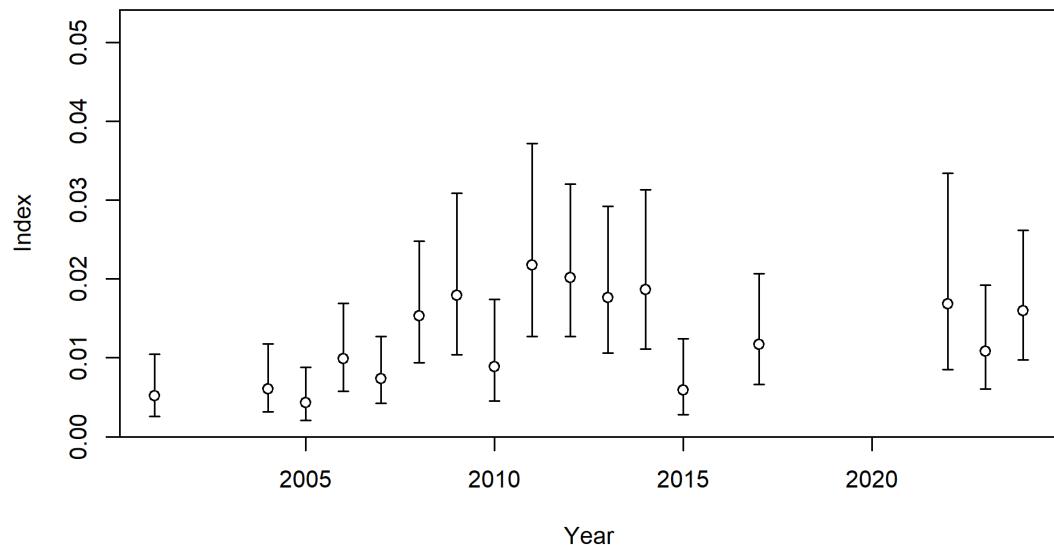

Figure 4: Annual relative index of abundance for the Oregon Onboard Observer (ORFS) index.

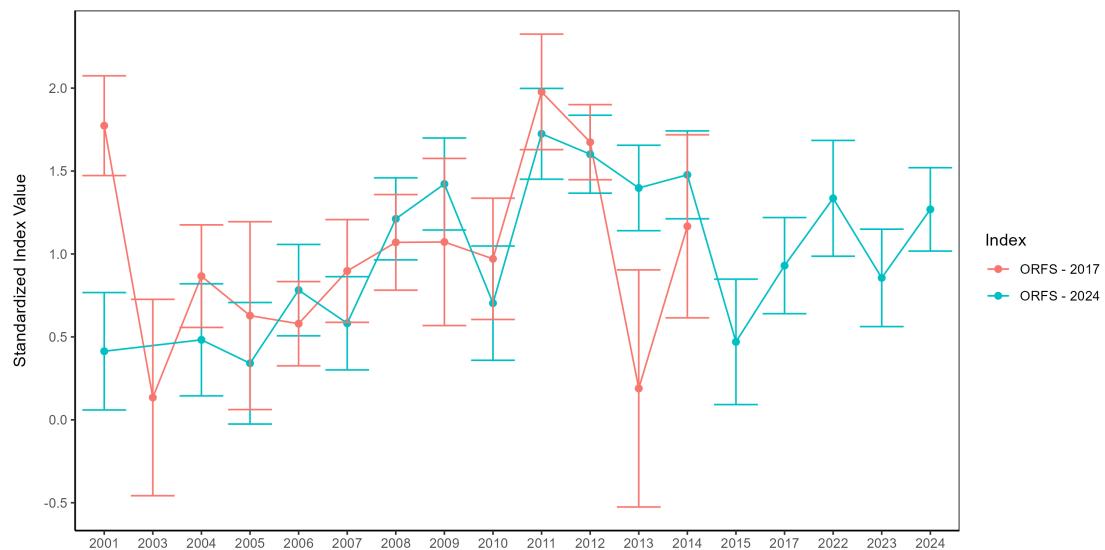

Figure 5: Comparison of Oregon Onboard Observer indices from the 2017 and the current assessment.

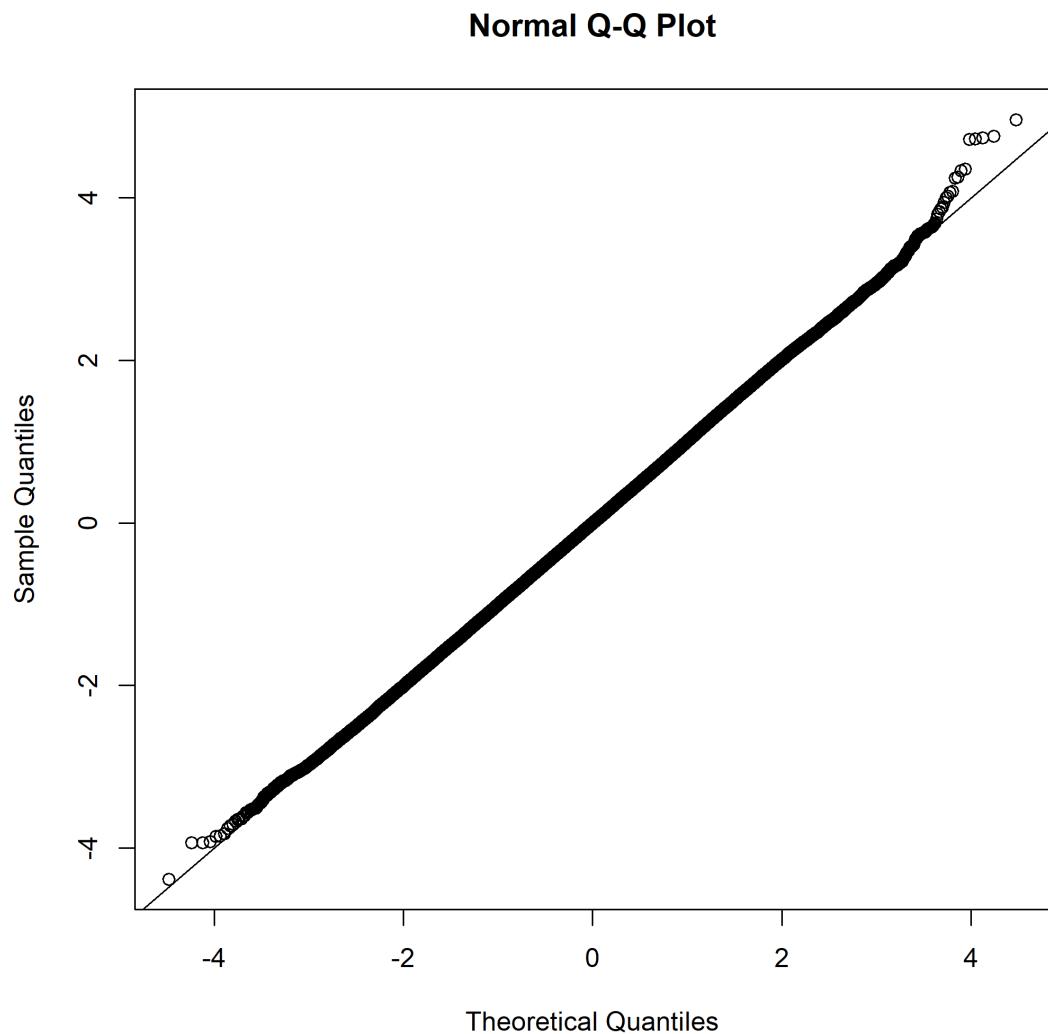

Figure 6: Quantile-quantile plot for the sdmTMB model fit for the updated portion of the Oregon recreational (ORBS) index.

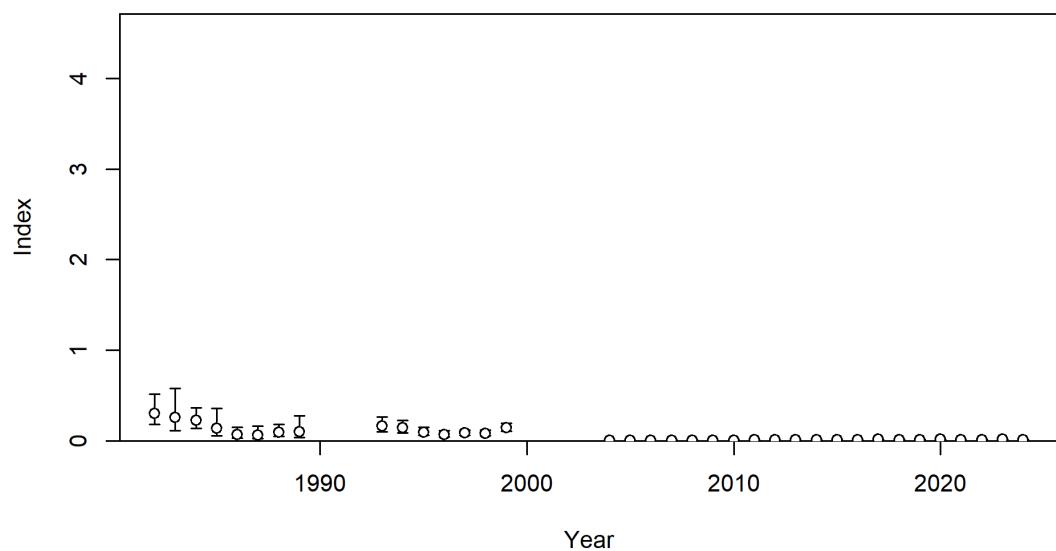

Figure 7: Annual relative index of abundance for the Oregon recreational index, including both MRFSS (1980 - 1999) and ORBS (2004 - 2024) indices.

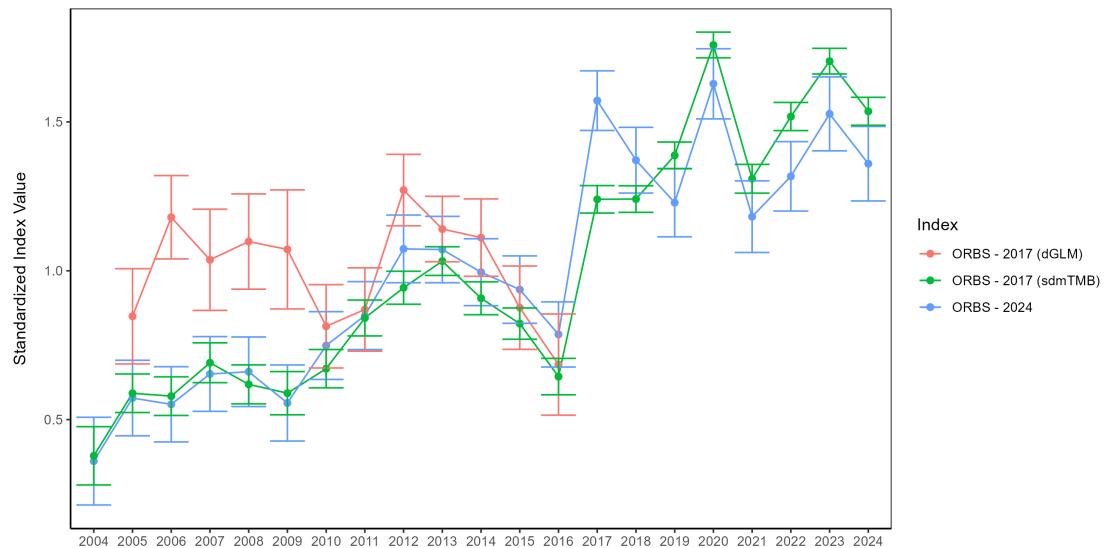

Figure 8: Comparison of the 2017 ORBS index (delta-GLM), the 2017 ORBS model (implemented in sdmTMB), and the current ORBS index (sdmTMB).

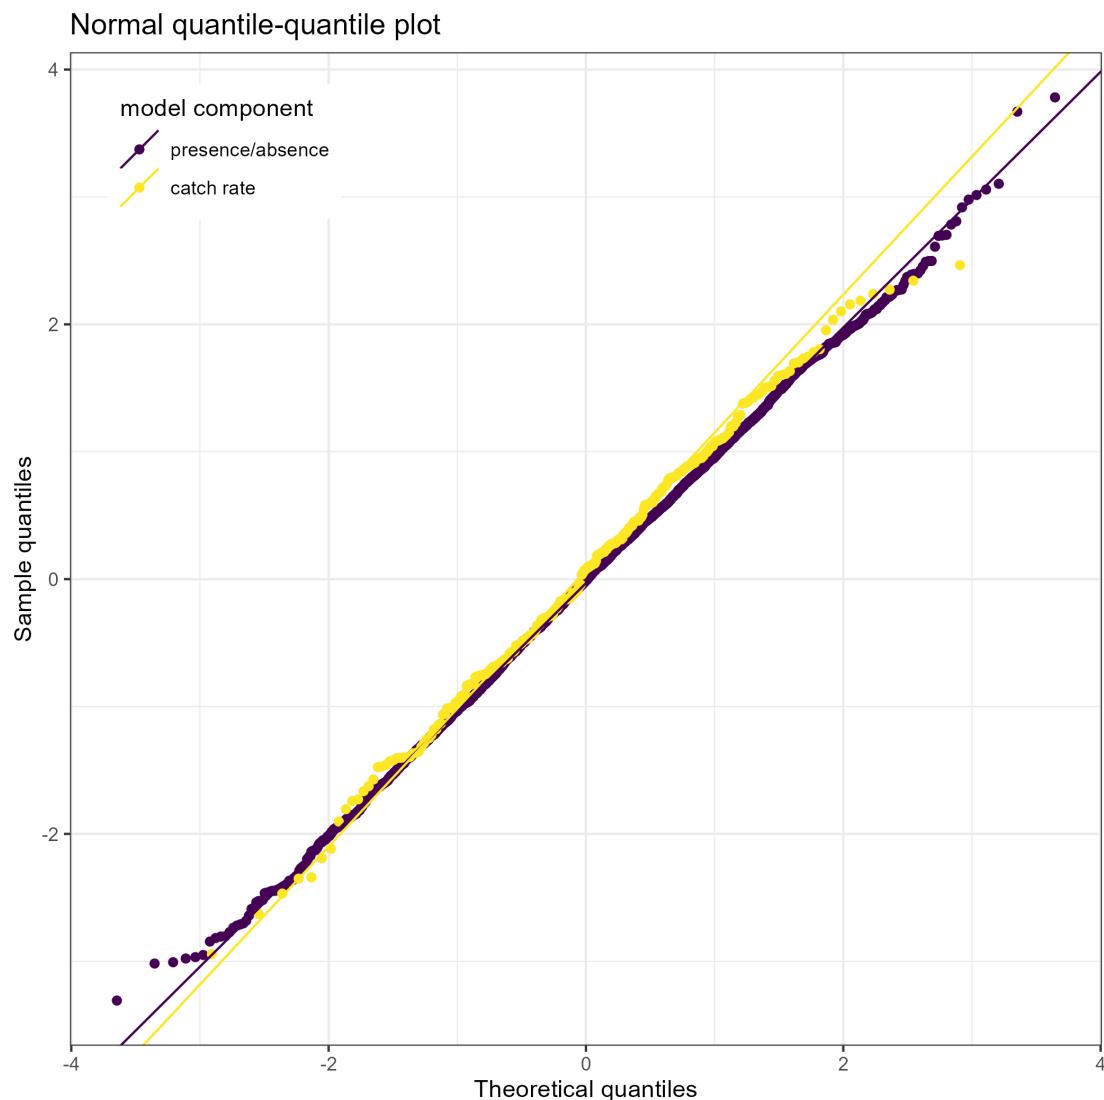

Figure 9: Quantile-quantile plot for the sdmTMB model fit for the NWFSC West Coast Groundfish Bottom Trawl Survey (WCGBTS) index.

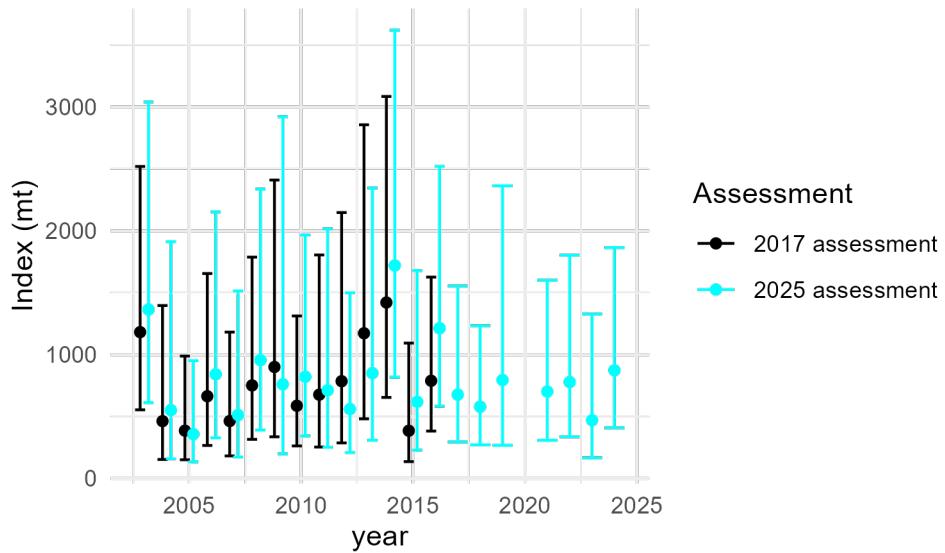

Figure 10: Comparison of the 2017 NWFSC West Coast Groundfish Bottom Trawl Survey (WCGBTS) and the current WCBTS index of abundance.

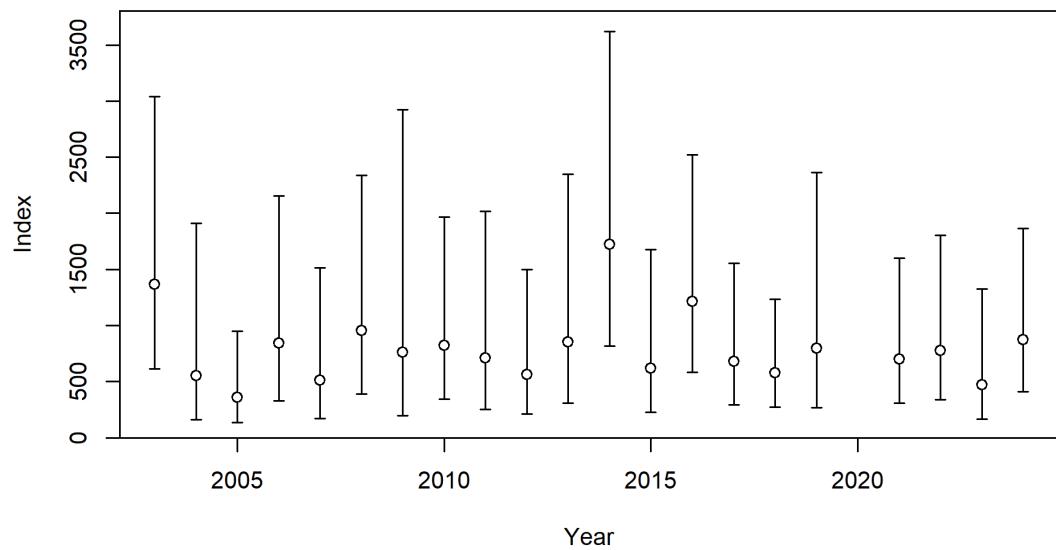

Figure 11: Annual relative index of abundance for the West Coast Groundfish Bottom Trawl Survey (WCGBTS).

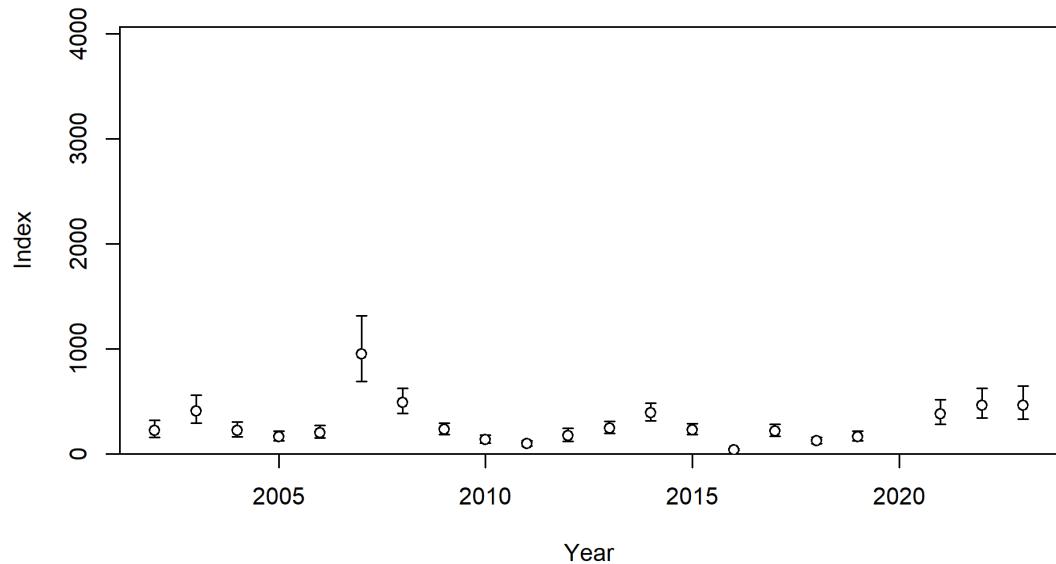

Figure 12: Annual relative index of abundance for the IPHC longline survey.

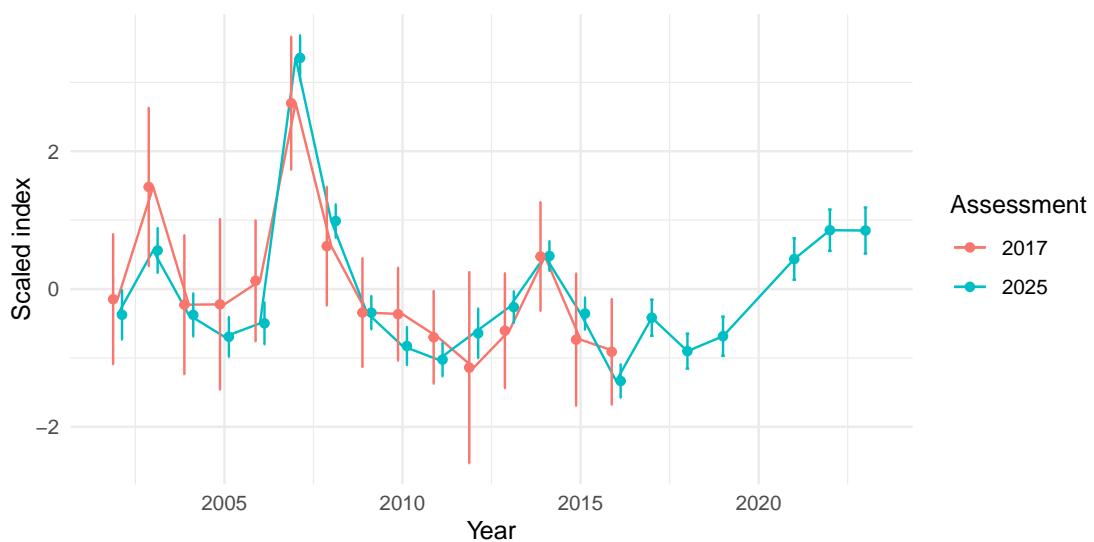

Figure 13: Comparison of the 2017 and the current IPHC index of abundance.

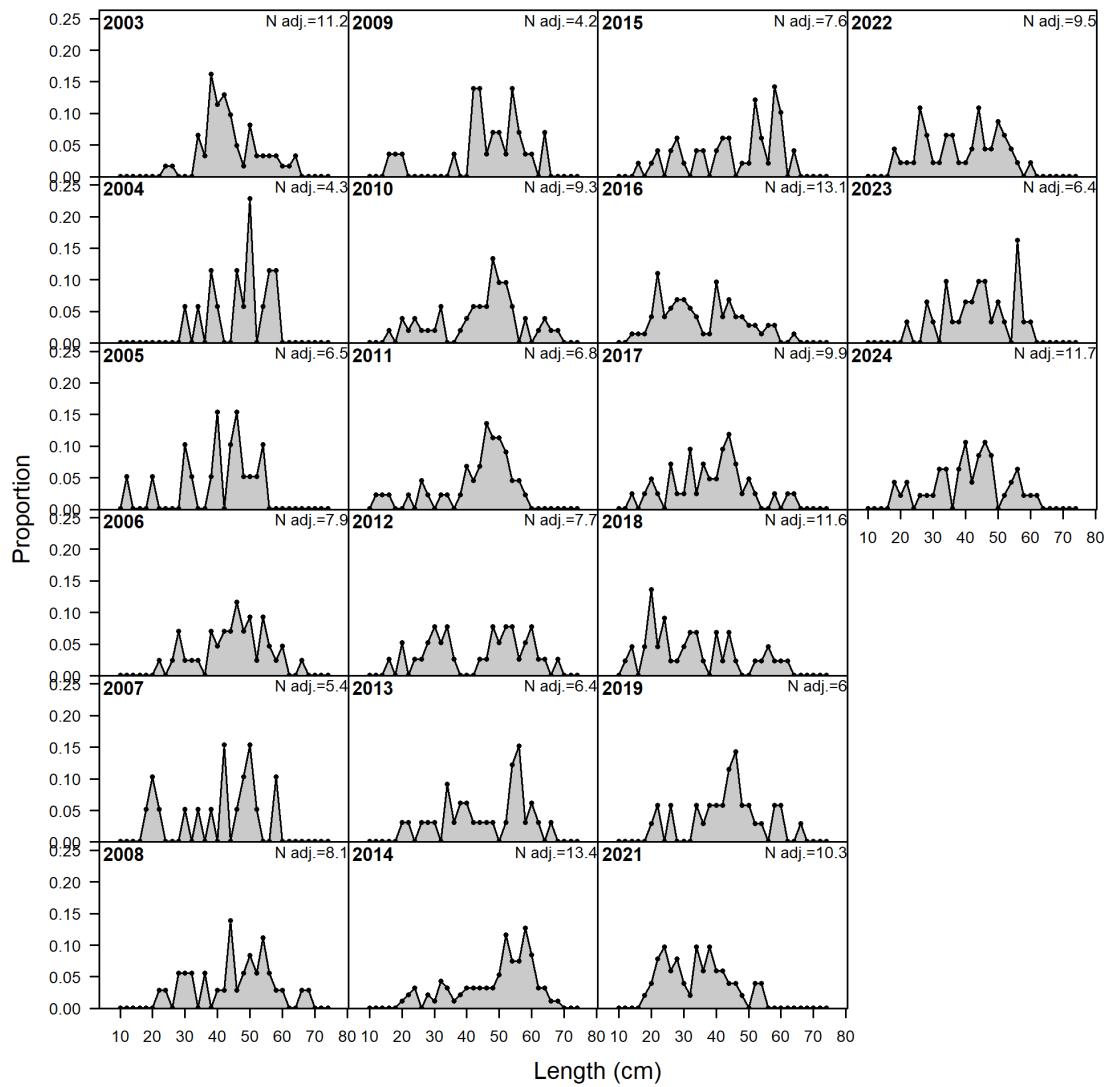

Figure 14: Annual length composition data for the WCBTS.

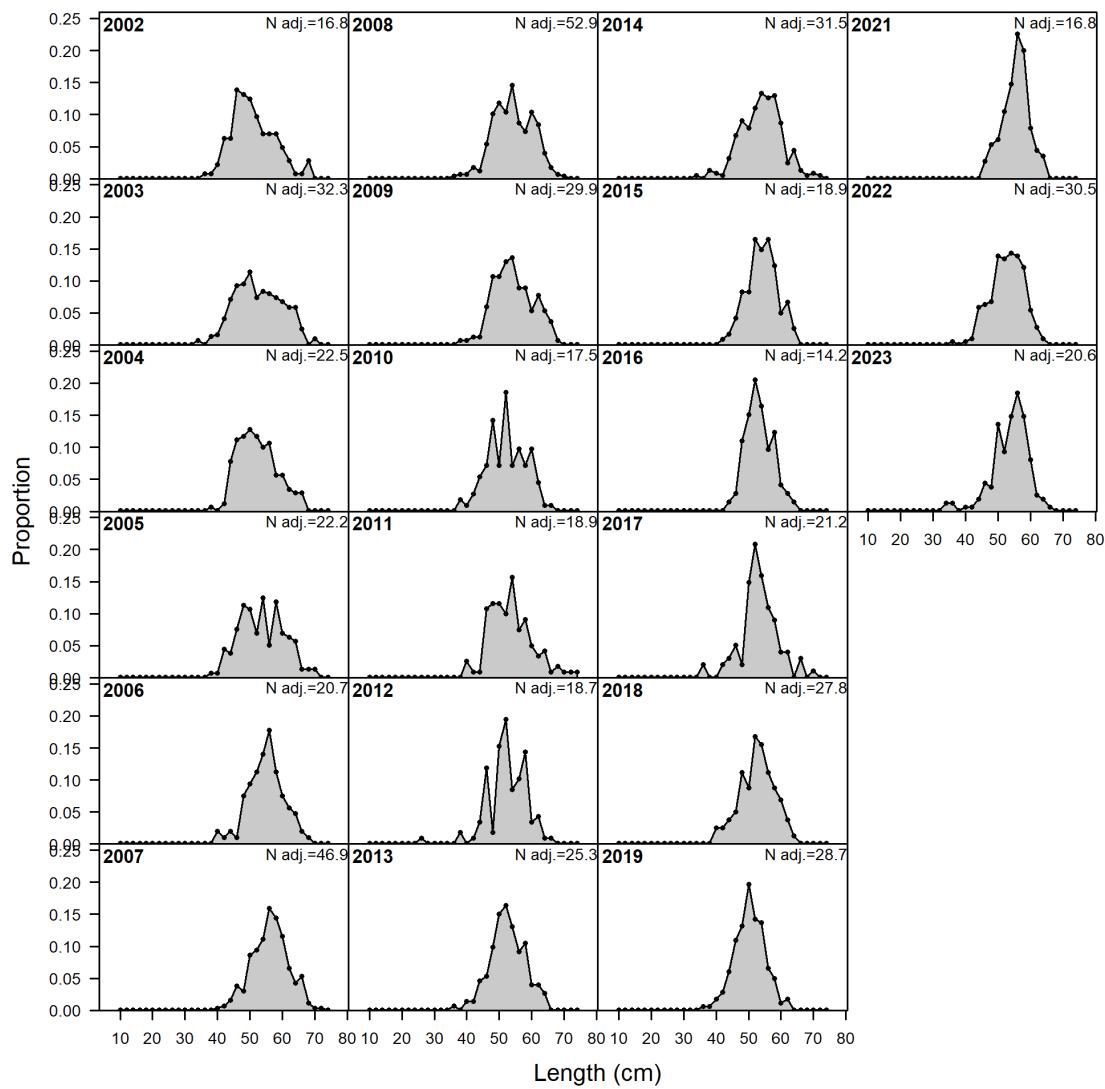

Figure 15: Annual length composition data from the IPHC longline survey.

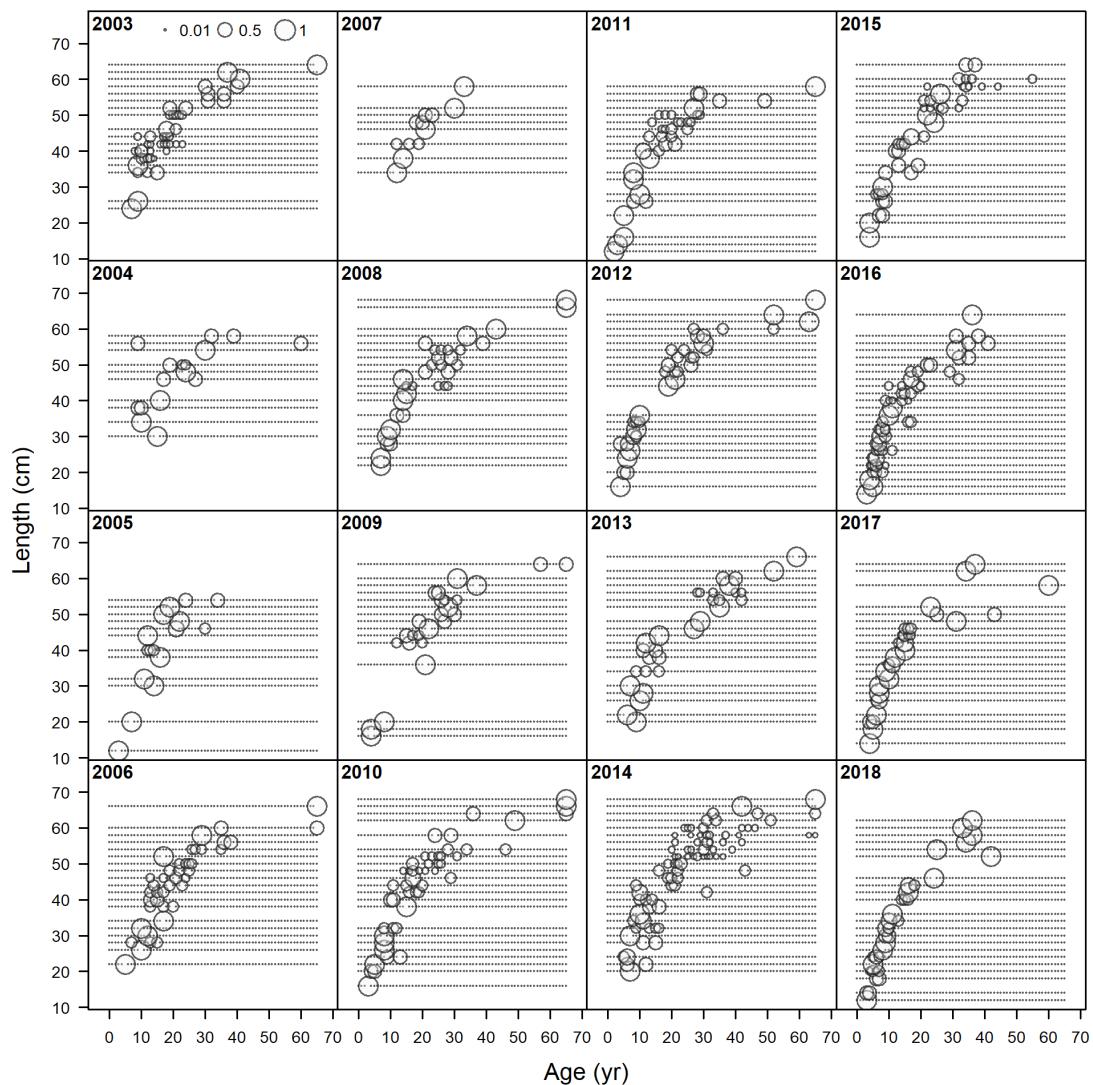

Figure 16: Annual unsexed conditional age-at-length data for the WCBTS (1 of 2).

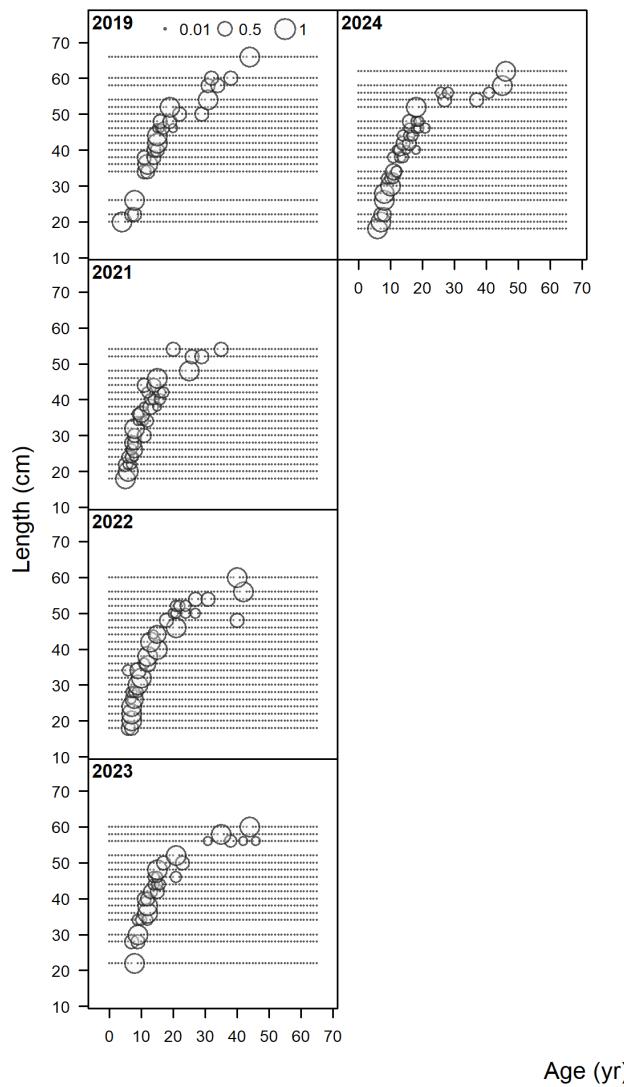

Figure 17: Annual unsexed conditional age-at-length data for the WCBTS (2 of 2).

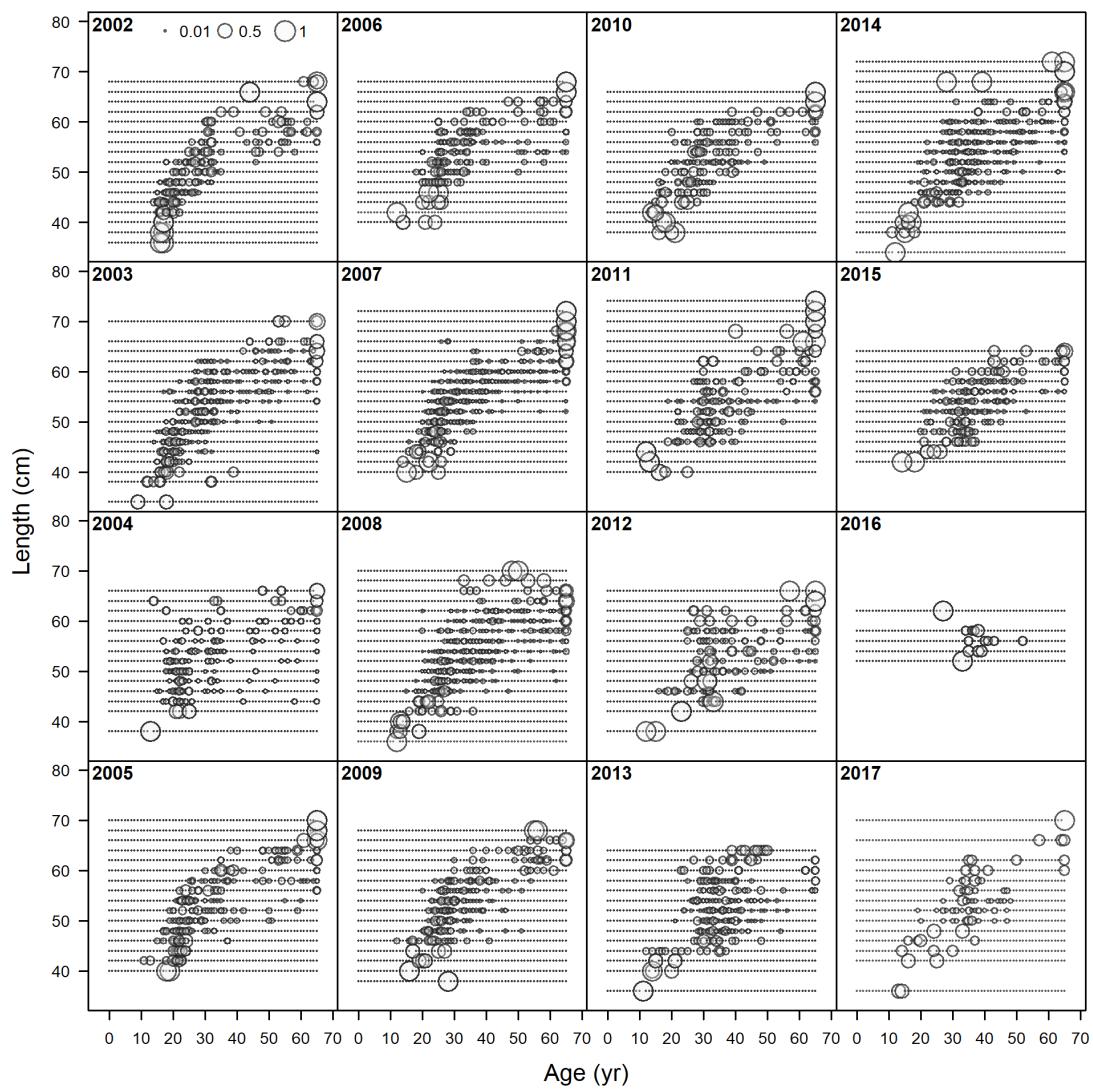

Figure 18: Annual unsexed conditional age-at-length data for the IPHC (1 of 2).

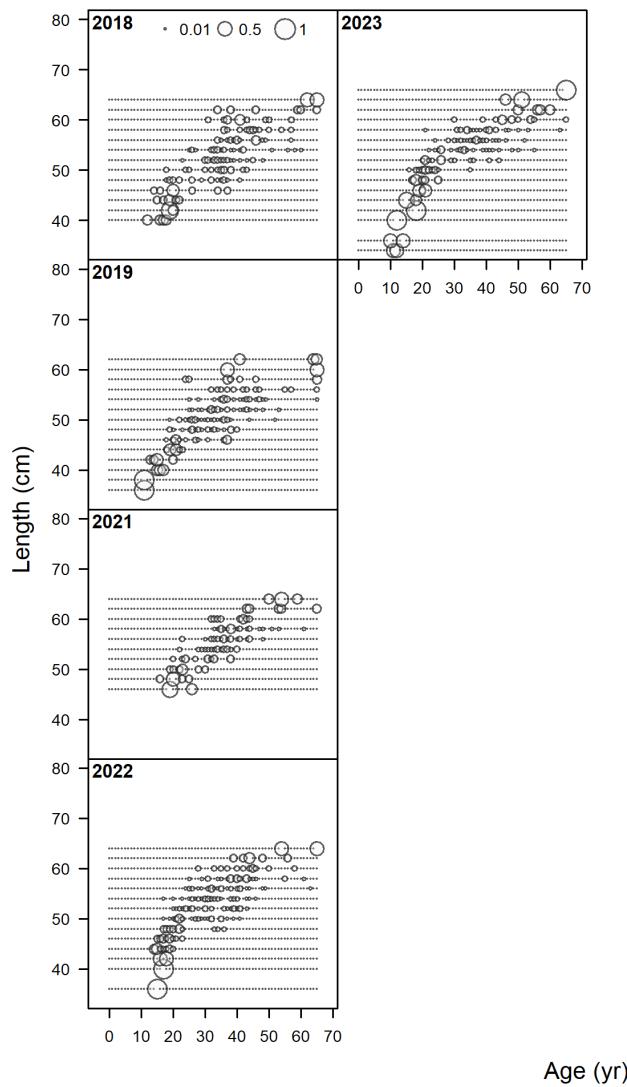

Figure 19: nnual unsexed conditional age-at-length data for the IPHC (1 of 2).

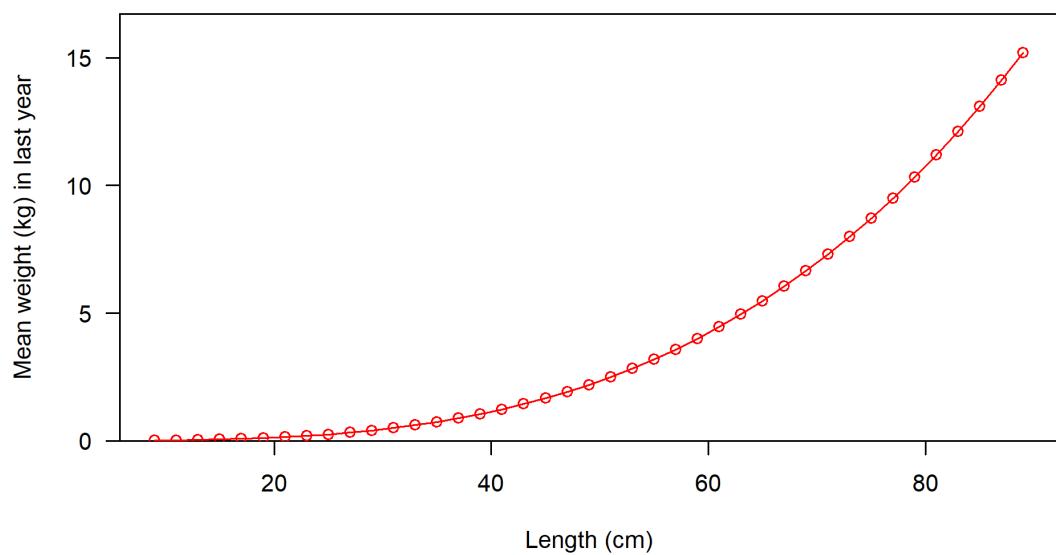

Figure 20: Updated weight-at-length relationship.

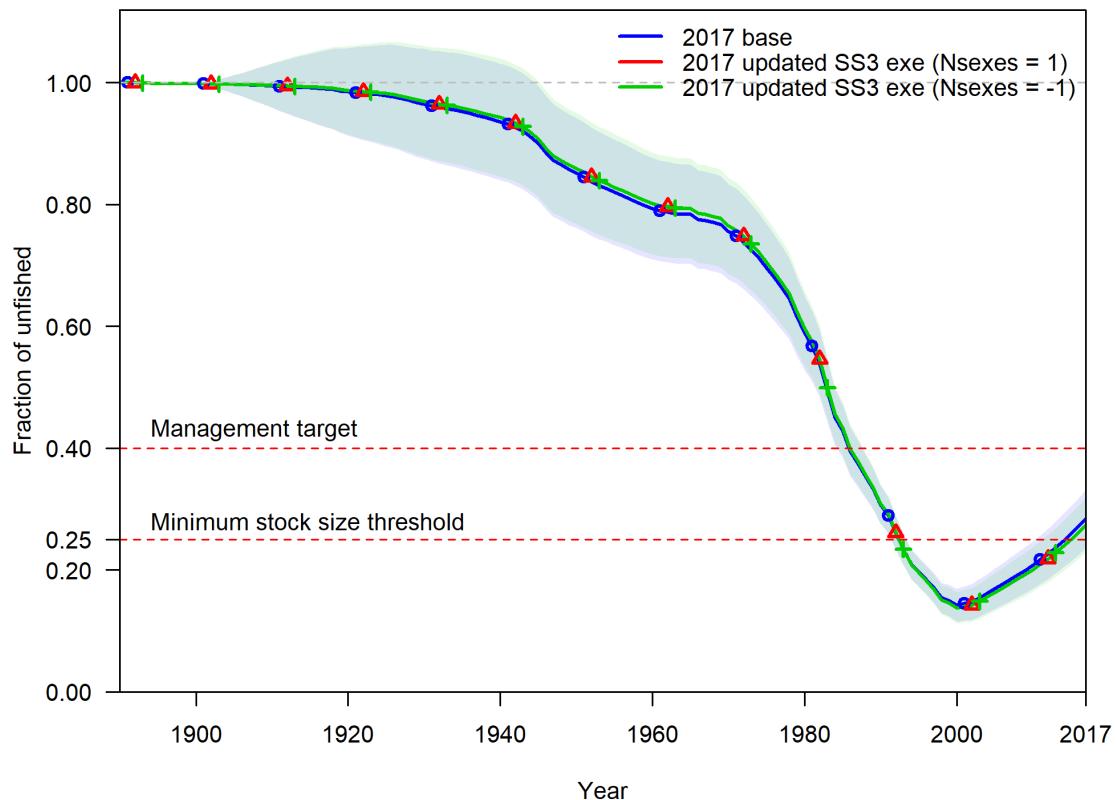

Figure 21: Comparison of the stock status for the 2017 model with the updated SS3 executable and a single-sex model.

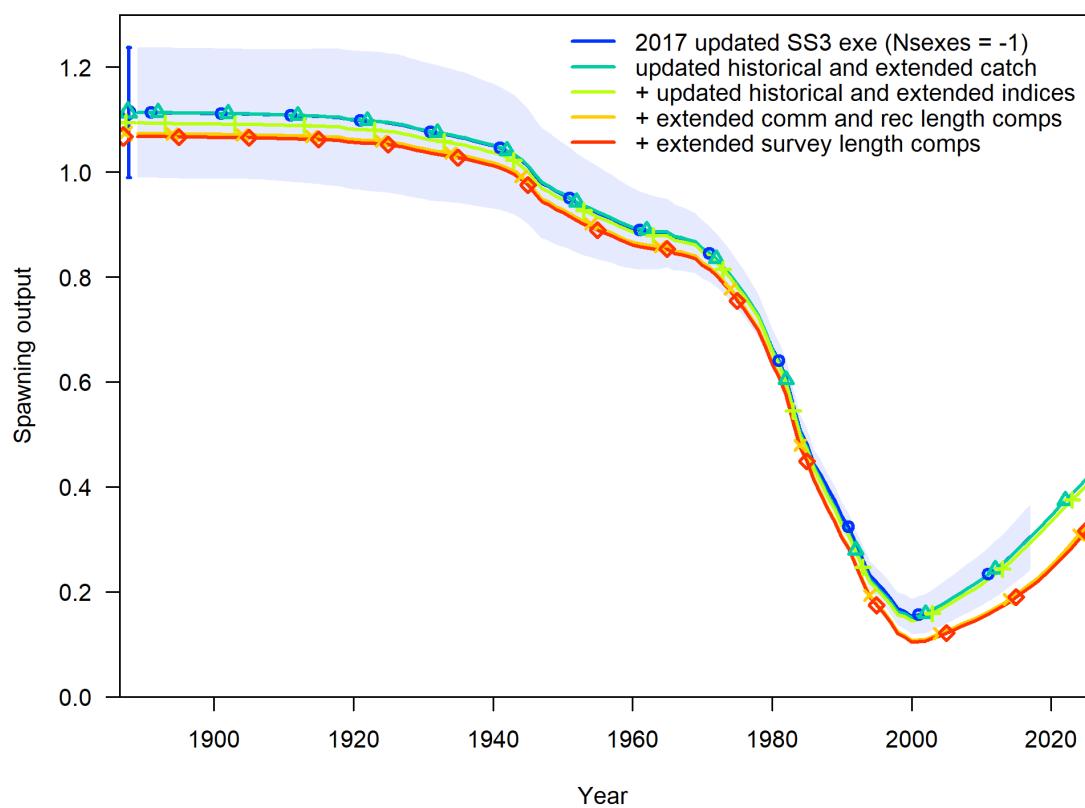

Figure 22: Comparison of the spawning output of the 2017 model with an updated SS3 executable (blue), updated catch data (dark green), updated indices (light green), new fishery length composition data (orange), and survey length composition data (red).

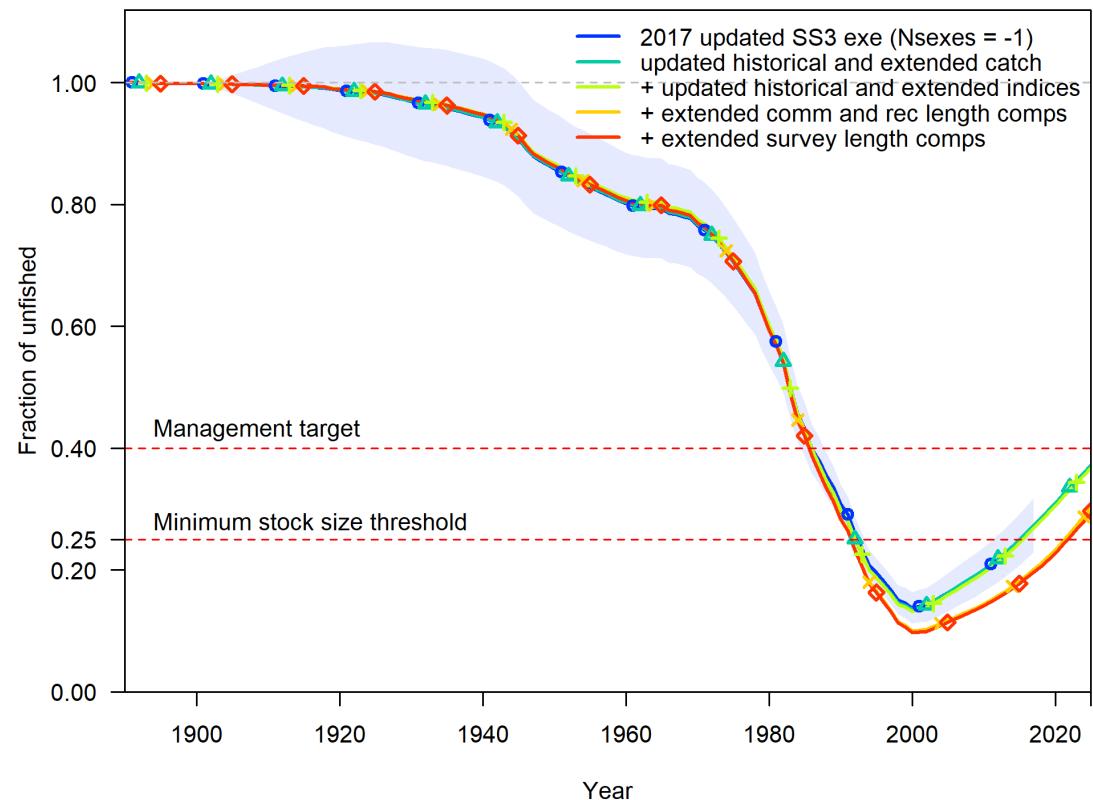

Figure 23: Comparison of the stock status of the 2017 model with an updated SS3 executable (blue), updated catch data (dark green), updated indices (light green), new fishery length composition data (orange), and survey length composition data (red).

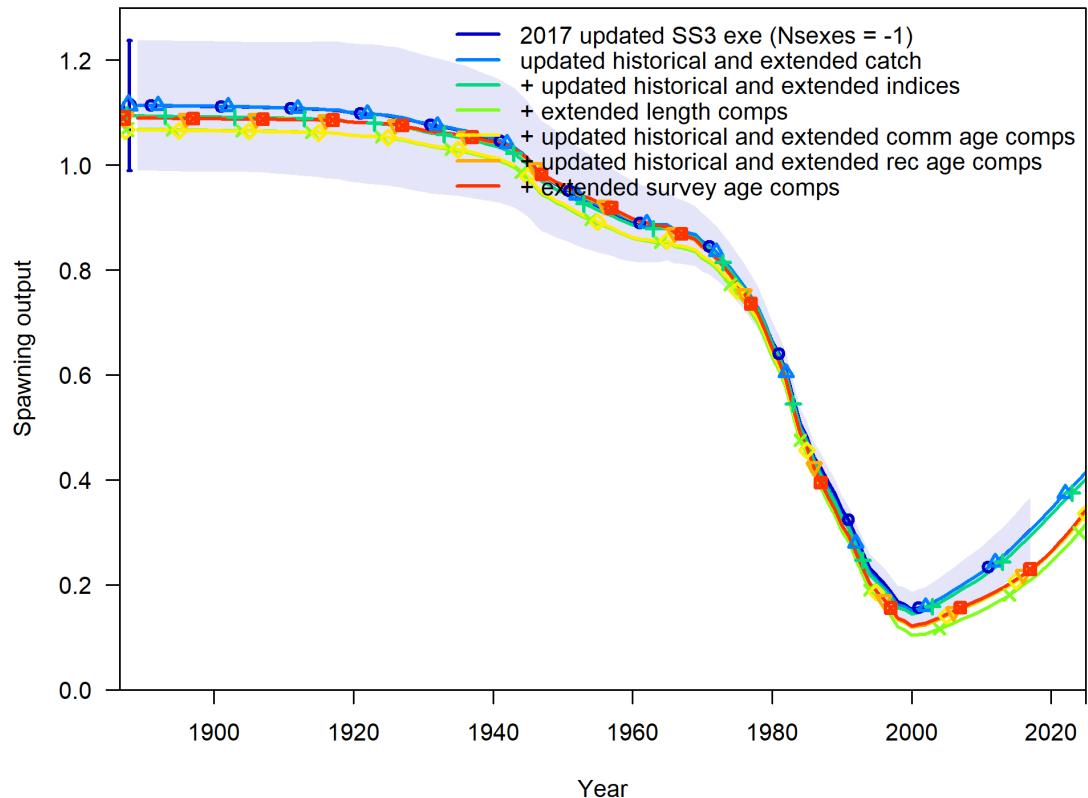

Figure 24: Comparison of the spawning output of the 2017 model with an updated SS3 executable (blue), updated catch data (light blue), updated indices (dark green), new fishery length composition data (light green), and commercial (yellow), recreational (orange), and survey (red) age composition data.

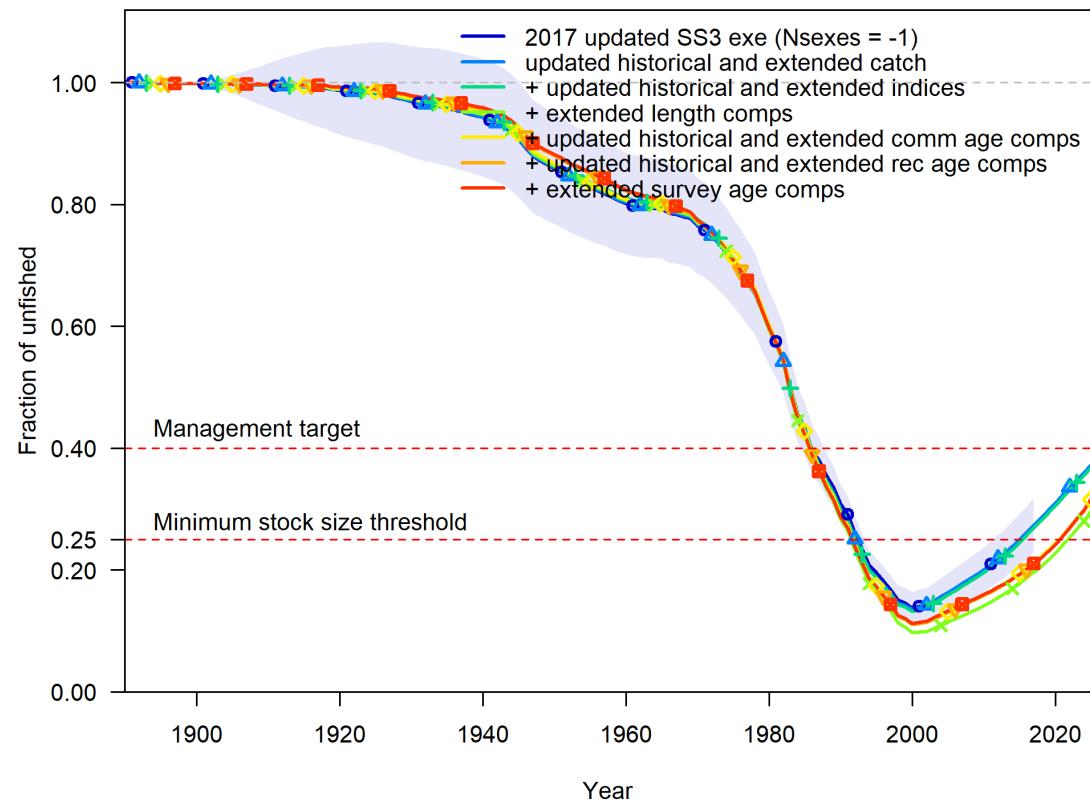

Figure 25: Comparison of the stock status of the 2017 model with an updated SS3 executable (blue), updated catch data (light blue), updated indices (dark green), new fishery length composition data (light green), and commercial (yellow), recreational (orange), and survey (red) age composition data.

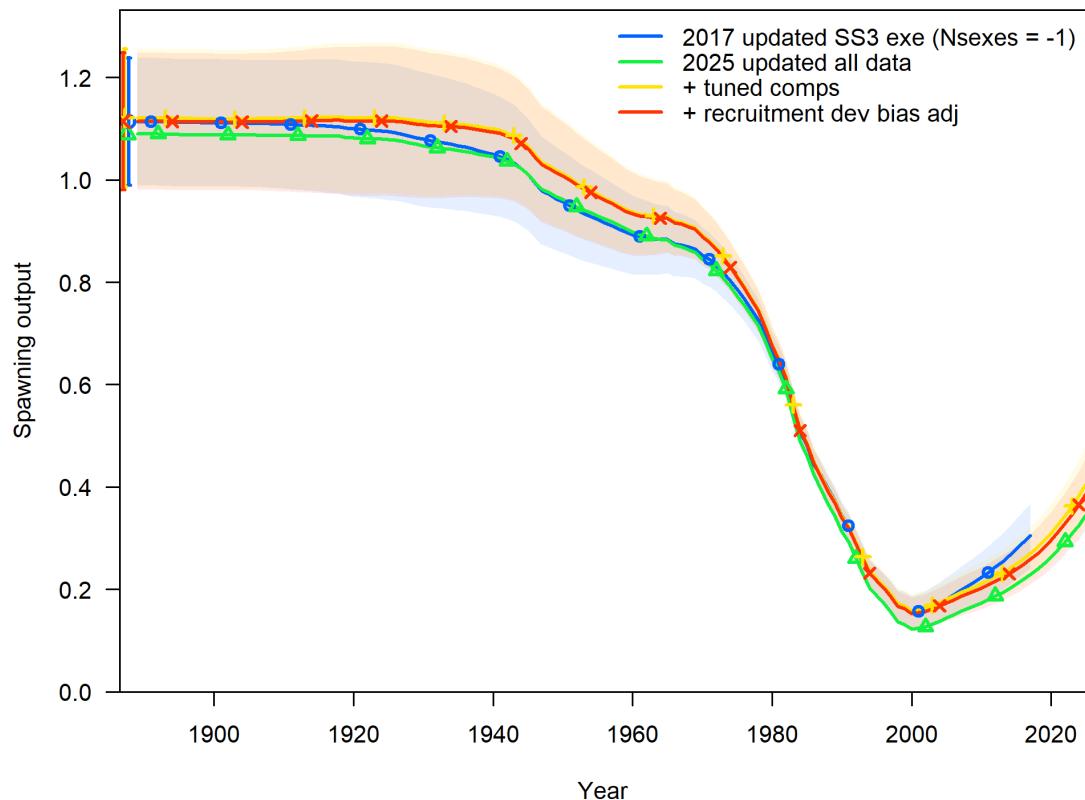

Figure 26: Comparison of the spawning output of the 2017 model with an updated SS3 executable (blue), 2025 model with all available updated data (green), with tuned compositional data (yellow), and with the updated recruitment bias adjustment ramp (red).

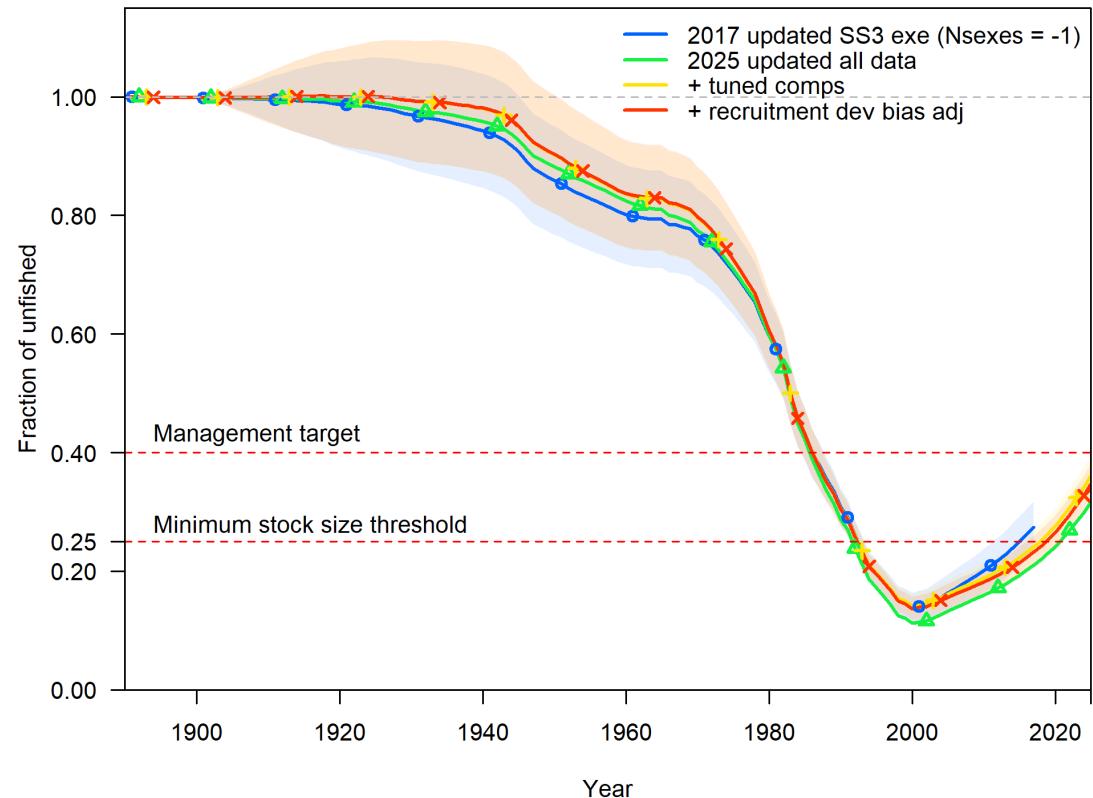

Figure 27: Comparison of the stock status of the 2017 model with an updated SS3 executable (blue), 2025 model with all available updated data (green), with tuned compositional data (yellow), and with the updated recruitment bias adjustment ramp (red).

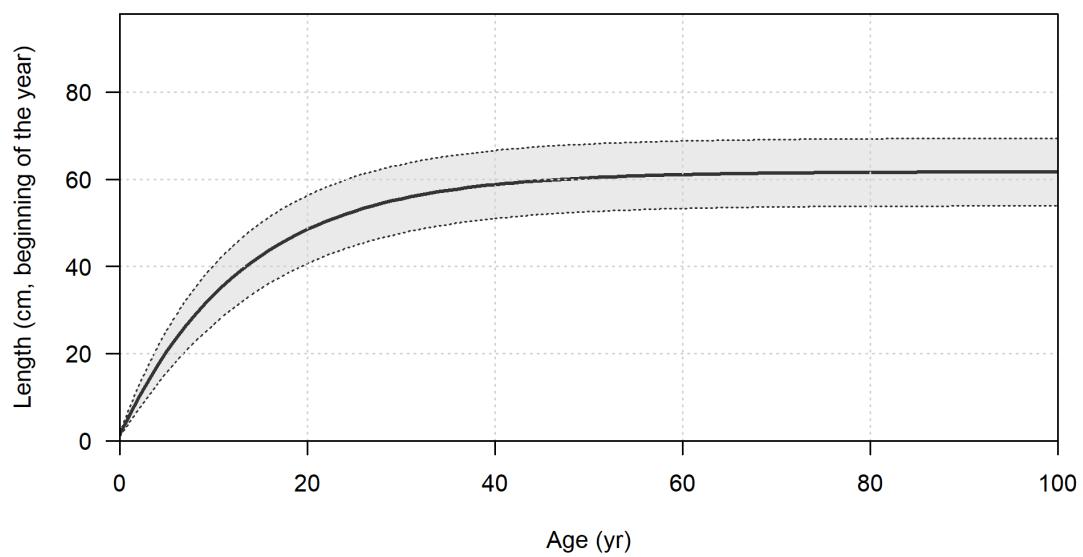

Figure 28: Length at age in the beginning of the year in the ending year of the model.

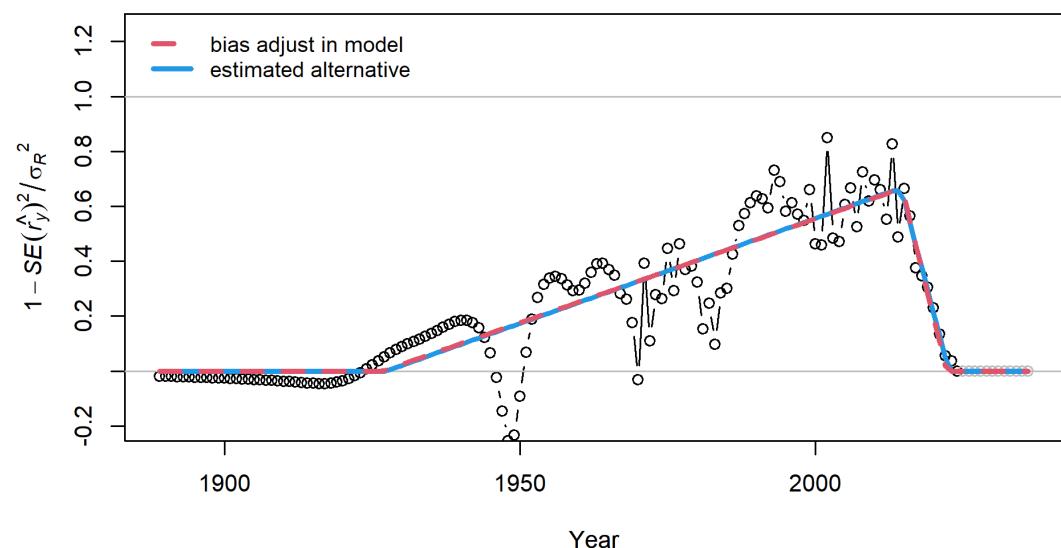

Figure 29: Points are transformed variances. Red line shows current settings for bias adjustment specified in the control file. Blue line shows least squares estimate of alternative bias adjustment relationship for recruitment deviations.

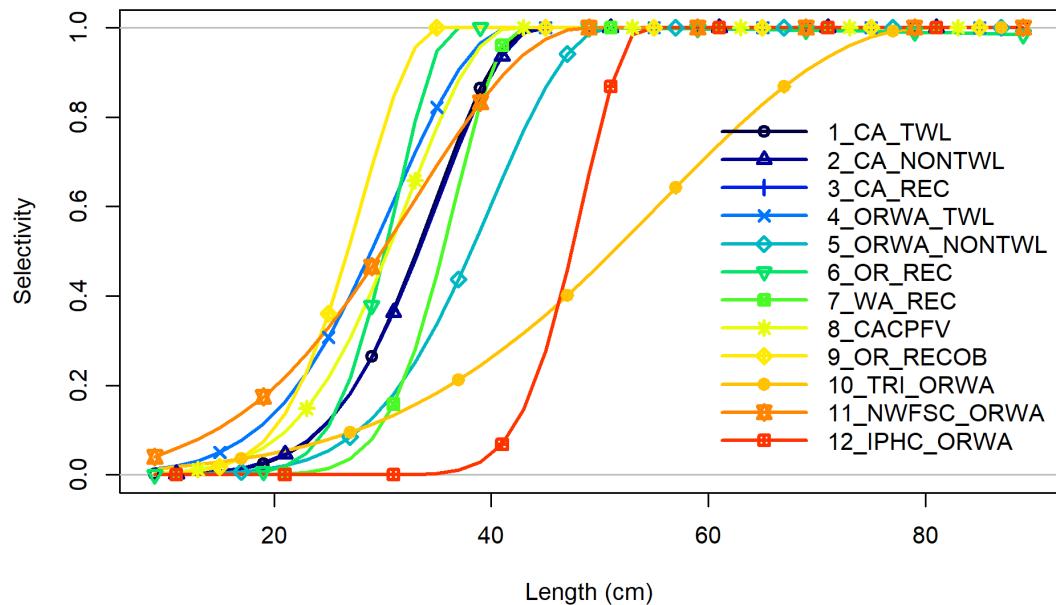

Figure 30: Estimated selectivity at length for all fleets.

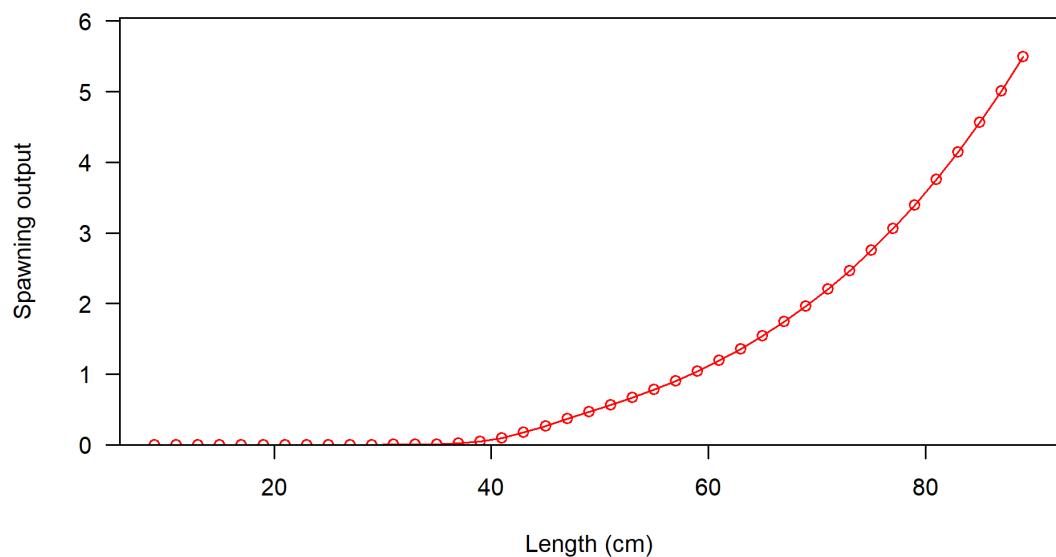

Figure 31: Spawning output at length.

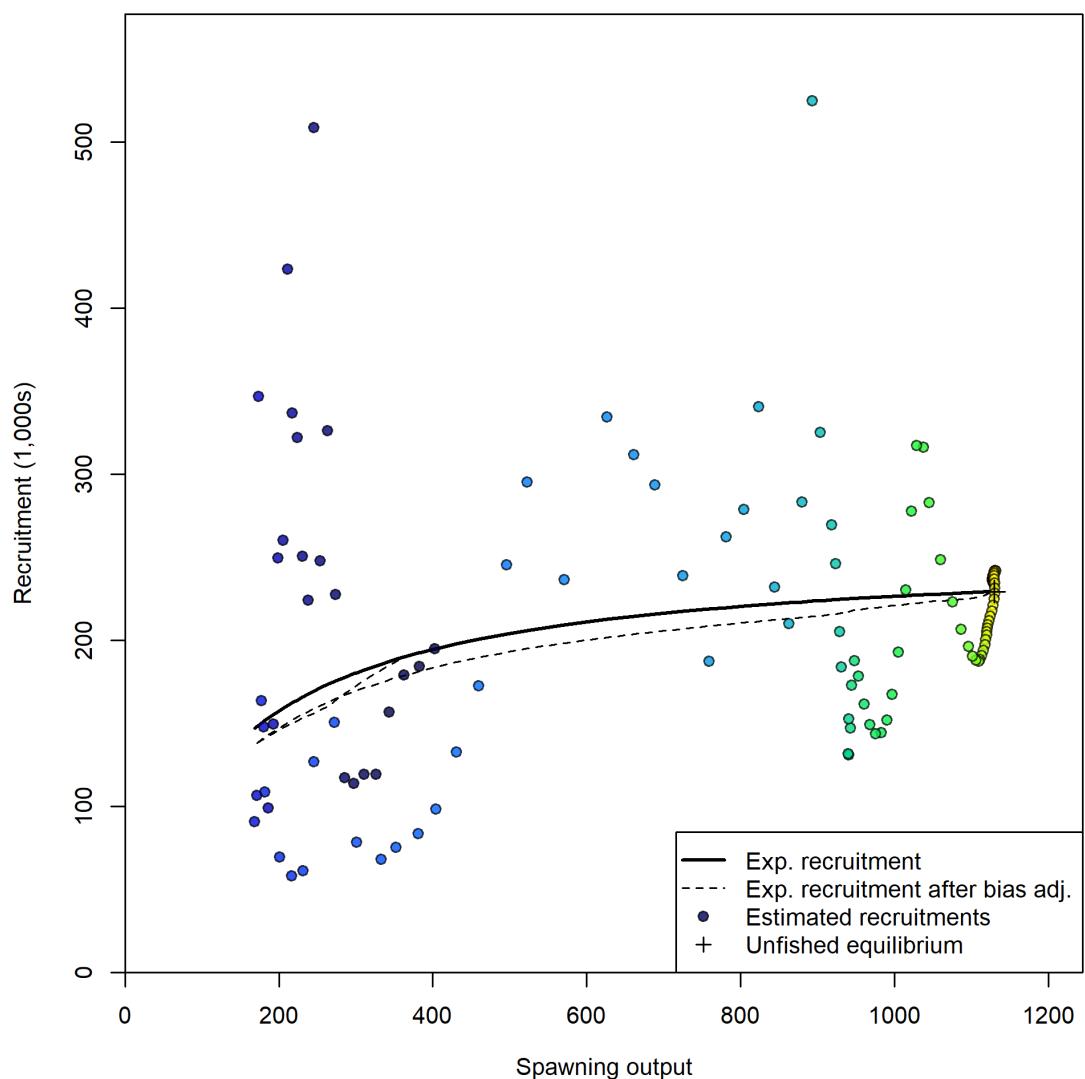

Figure 32: Stock-recruit curve. Point colors indicate year, with warmer colors indicating earlier years and cooler colors in showing later years.

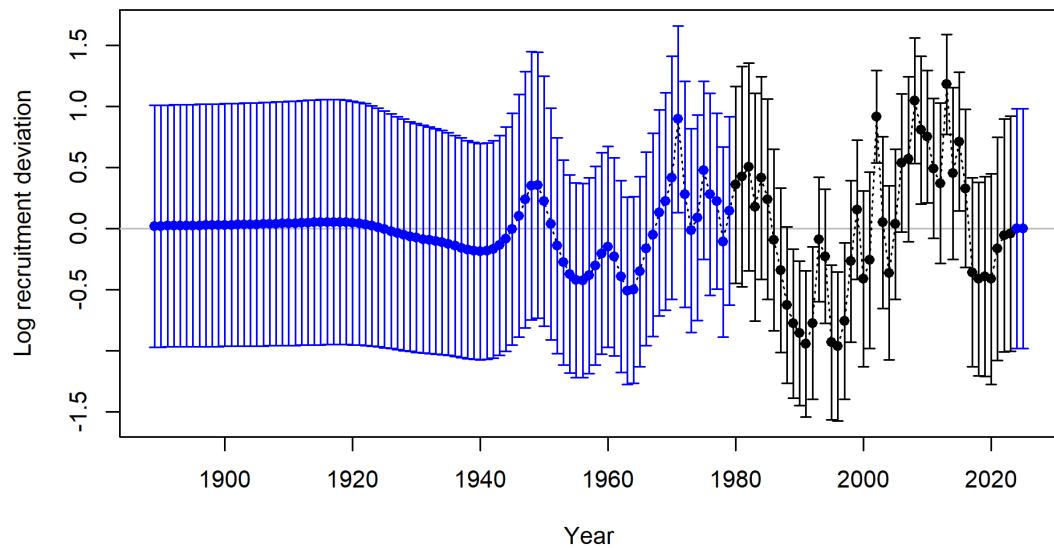

Figure 33: Estimated recruitment deviations with 95% intervals.

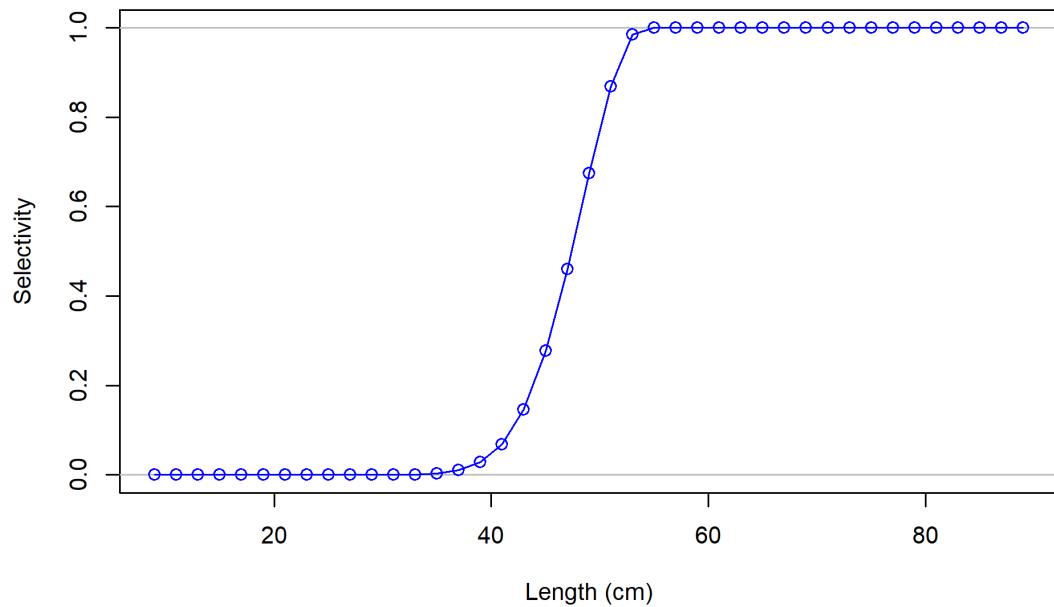

Figure 34: Estimated selectivity for the IPHC longline survey for Oregon/Washington (Fleet 12).

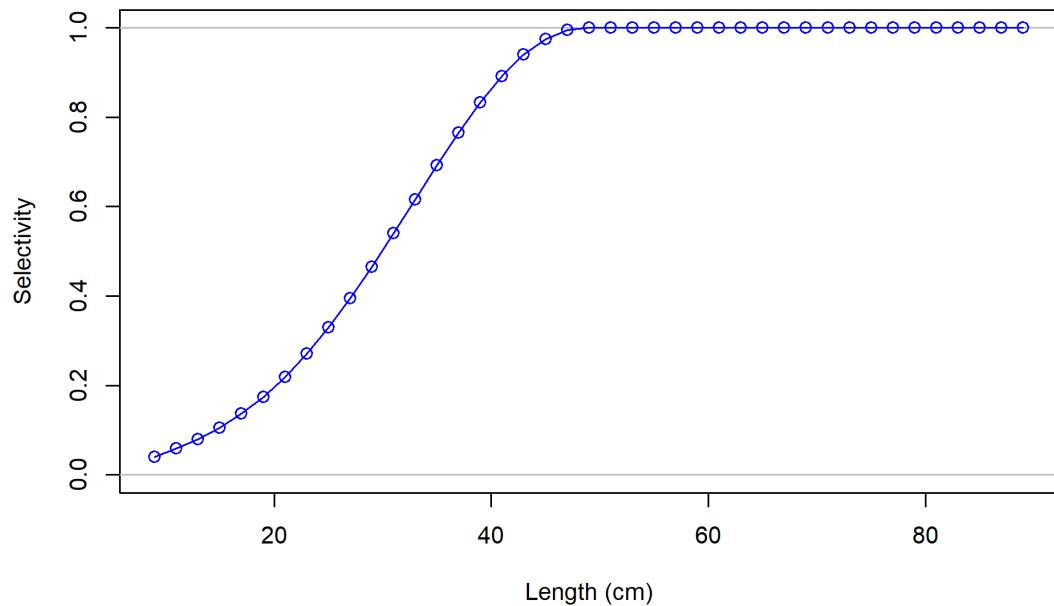

Figure 35: Estimated selectivity for the WCBTS for Oregon/Washington (Fleet 11).

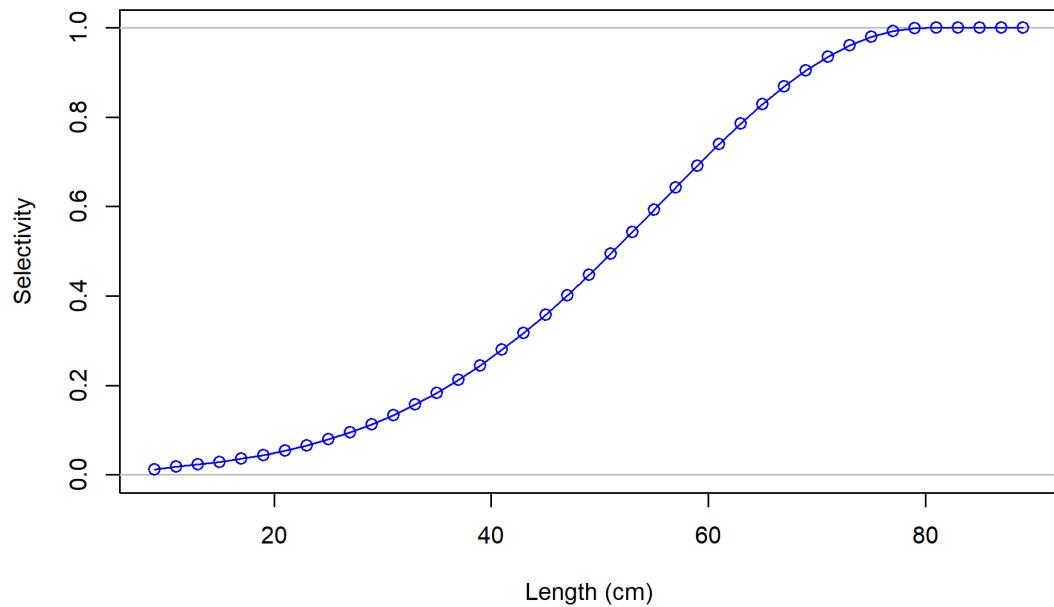

Figure 36: Estimated selectivity for the Triennial bottom trawl survey for Oregon/Washington (Fleet 10).

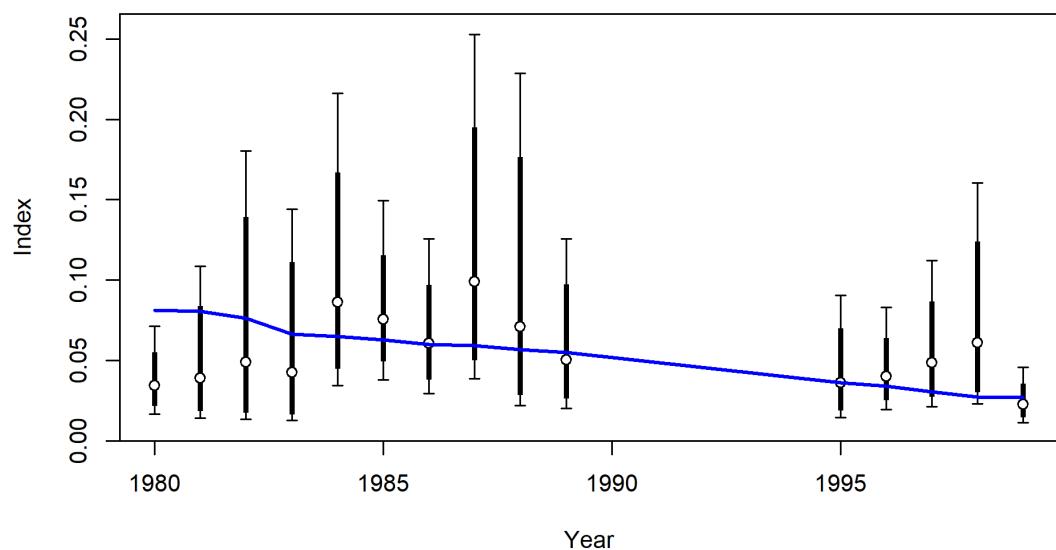

Figure 37: Fit to the California MRFSS recreational index.

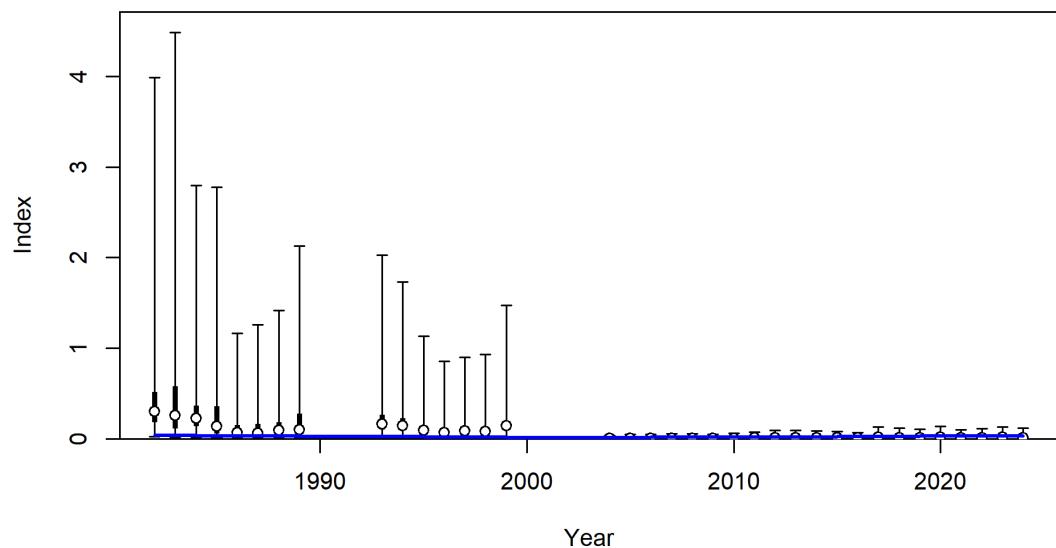

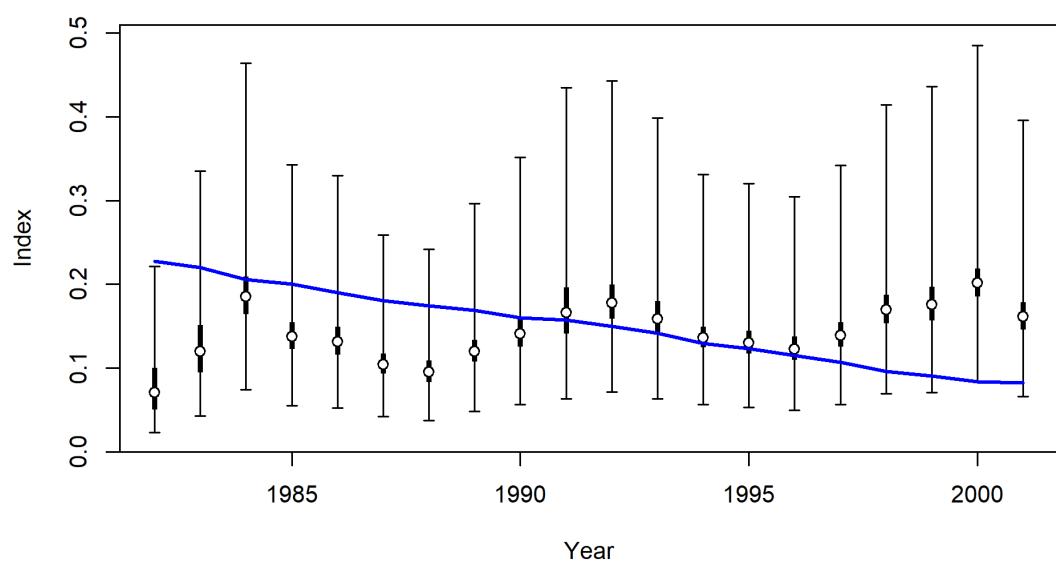

Figure 38: Fit to the Oregon recreational index.

Figure 39: Fit to the Washington recreational index.

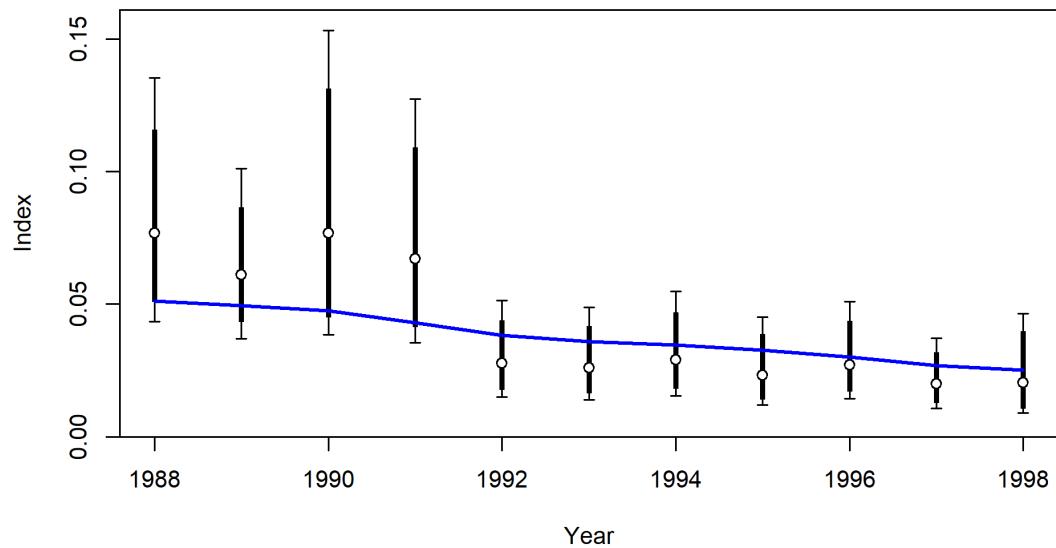

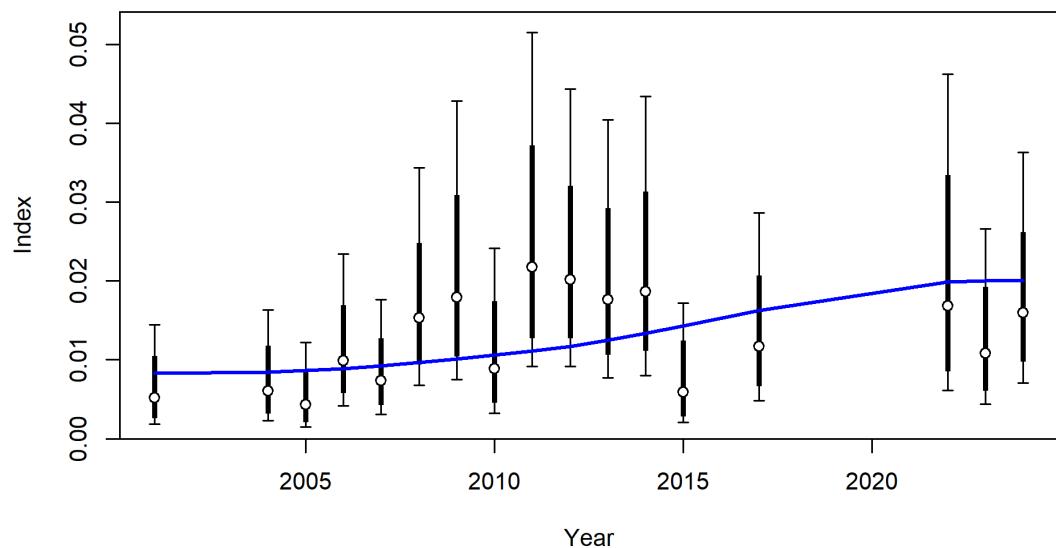

Figure 40: Fit to the California CPFV observer index.

Figure 41: Fit to the Oregon onboard observer (ORFS) index.

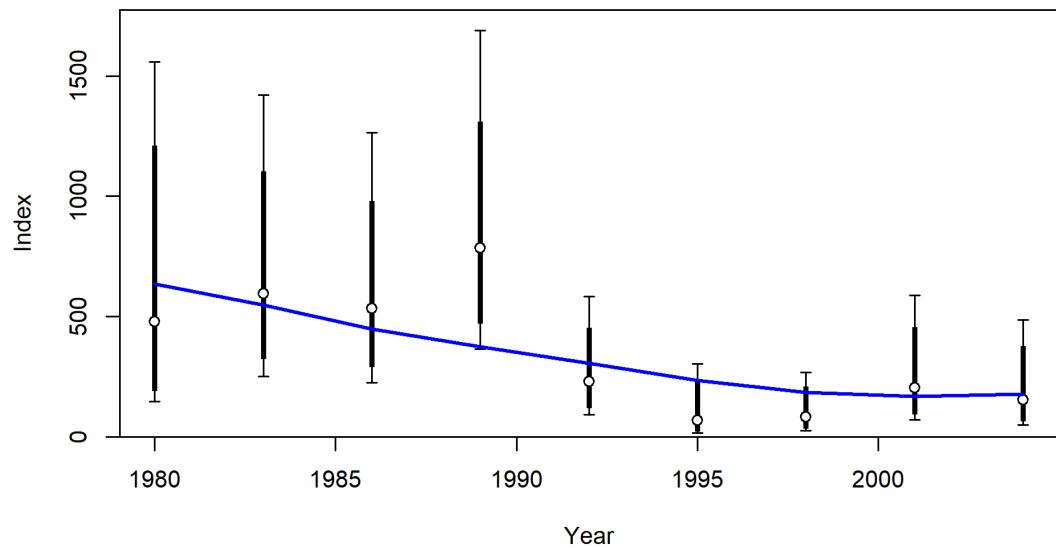

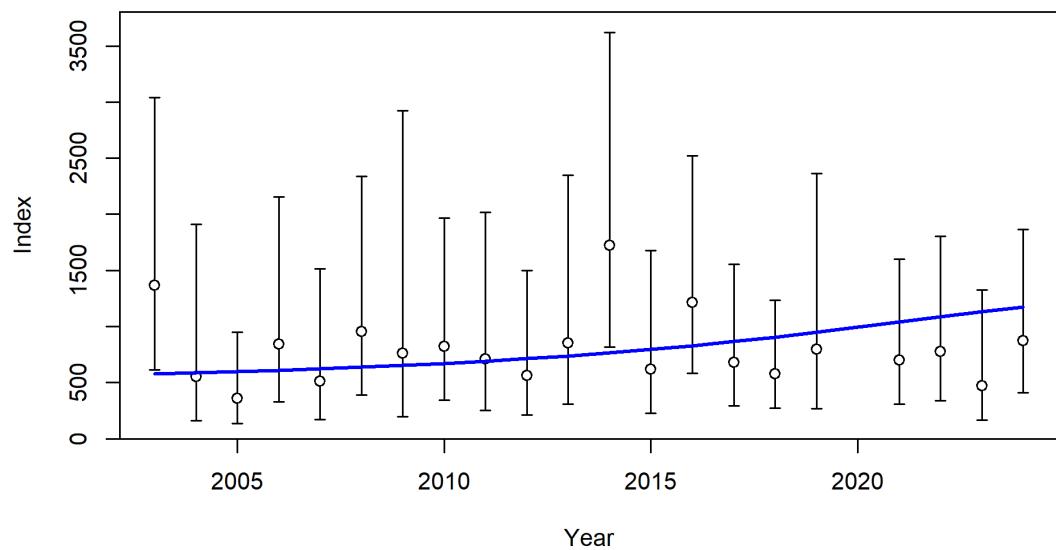

Figure 42: Fit to the Triennial survey index.

Figure 43: Fit to the WCBTS index.

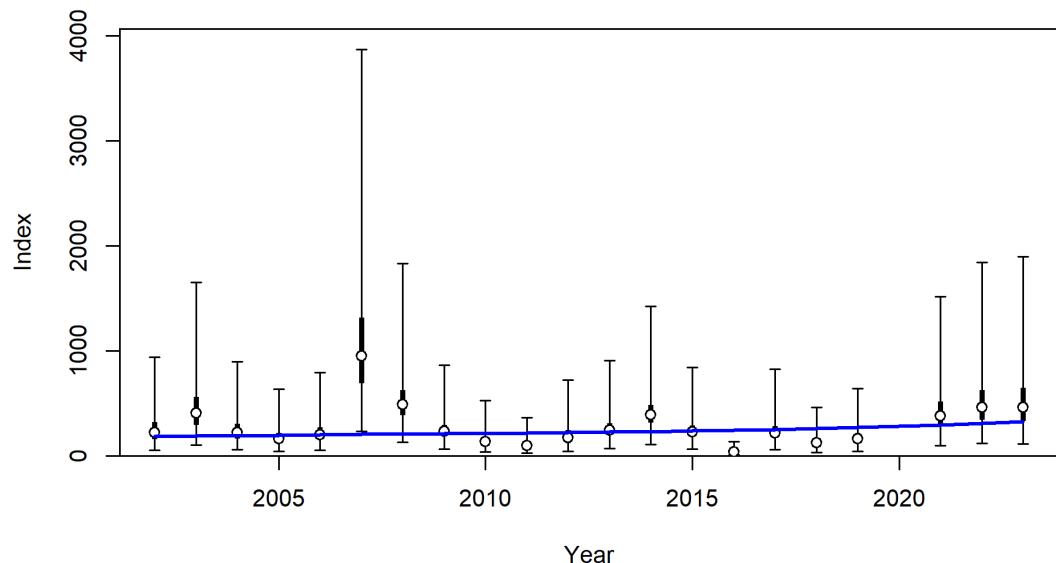

Figure 44: Fit to the IPHC survey index.

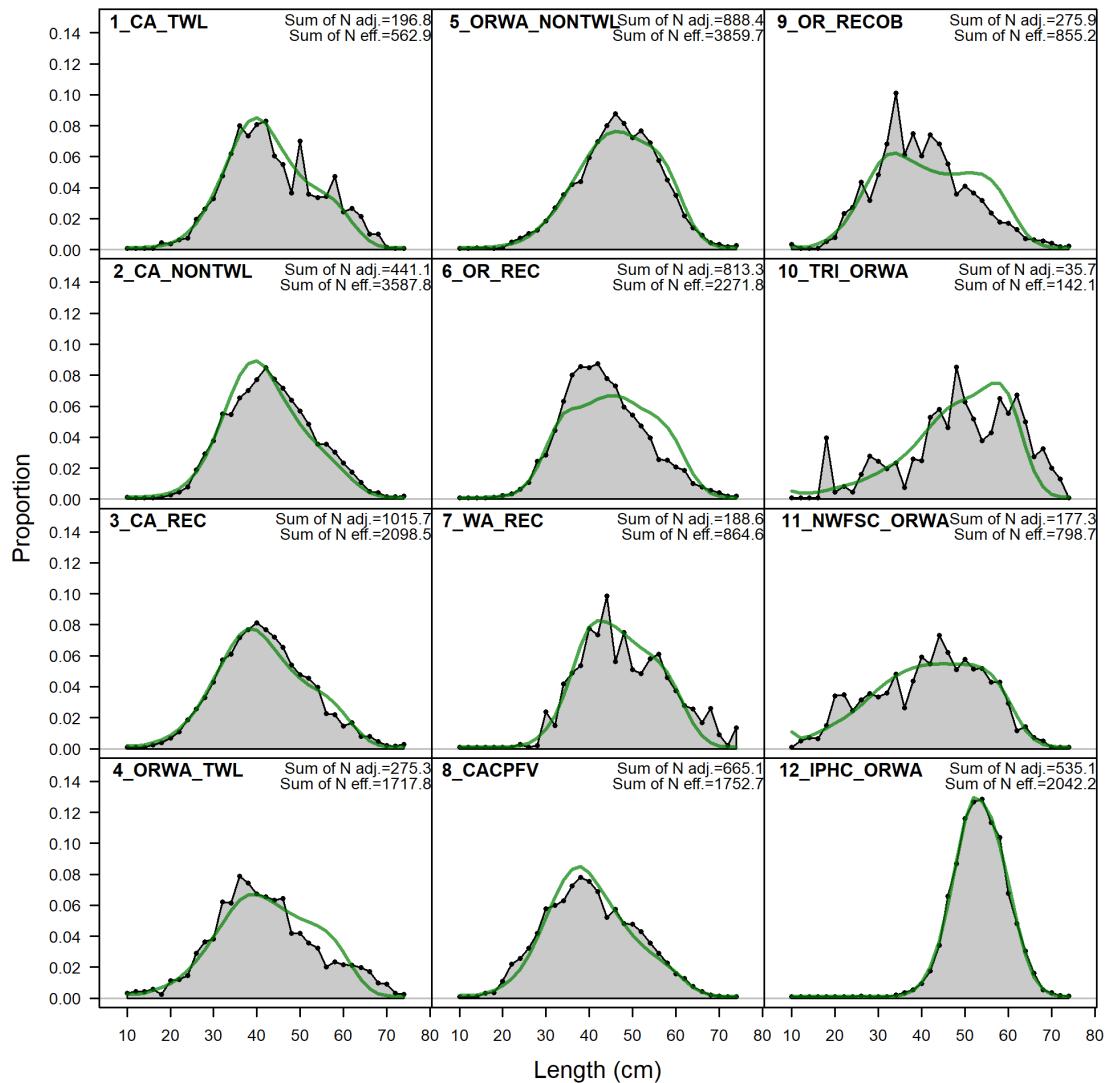

Figure 45: Fit to length composition data, aggregated across time by fleet.

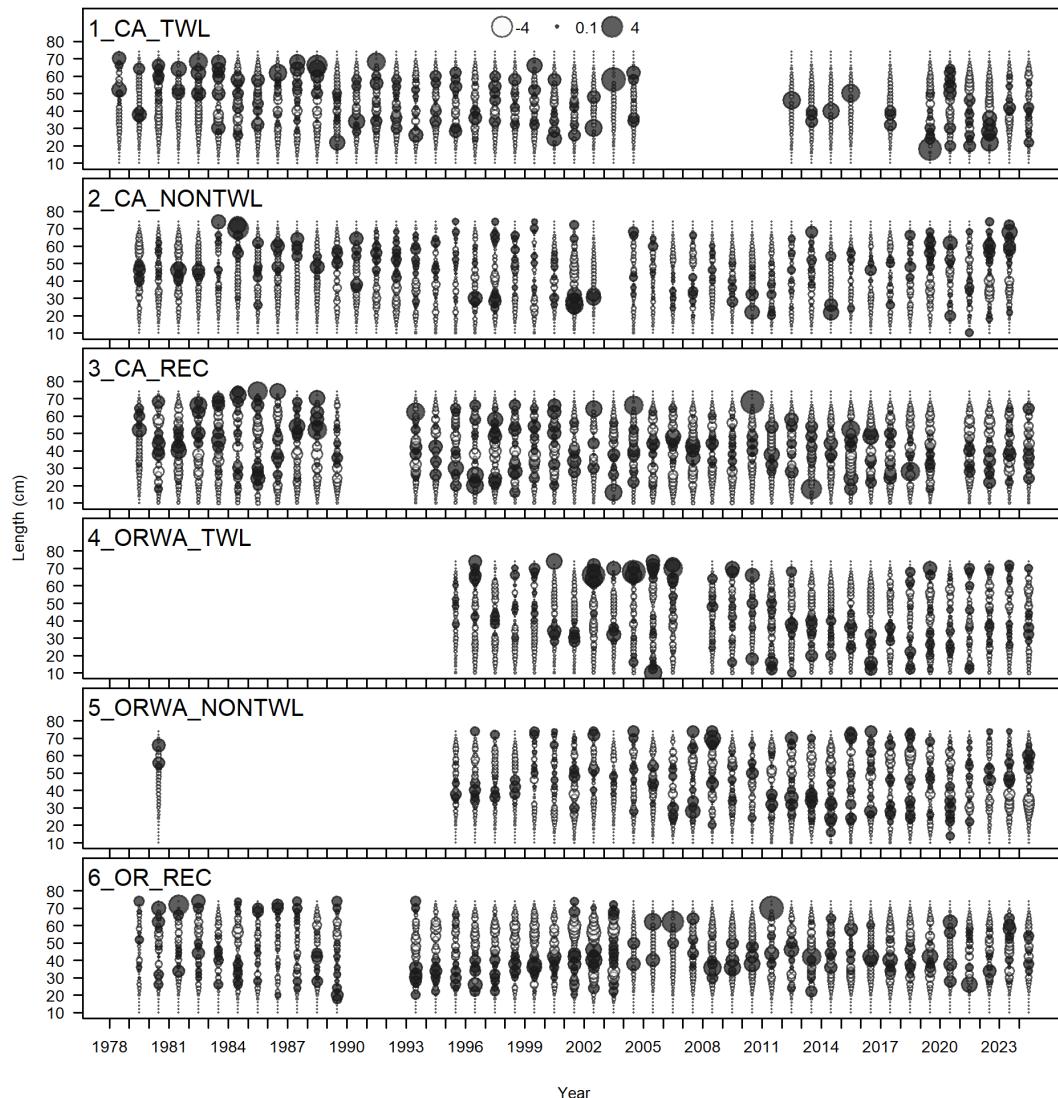

Figure 46: Pearson residuals, comparing across fleets, for length composition data (1 of 2). Closed bubbles are positive residuals (observed > expected) and open bubbles are negative residuals (observed < expected).

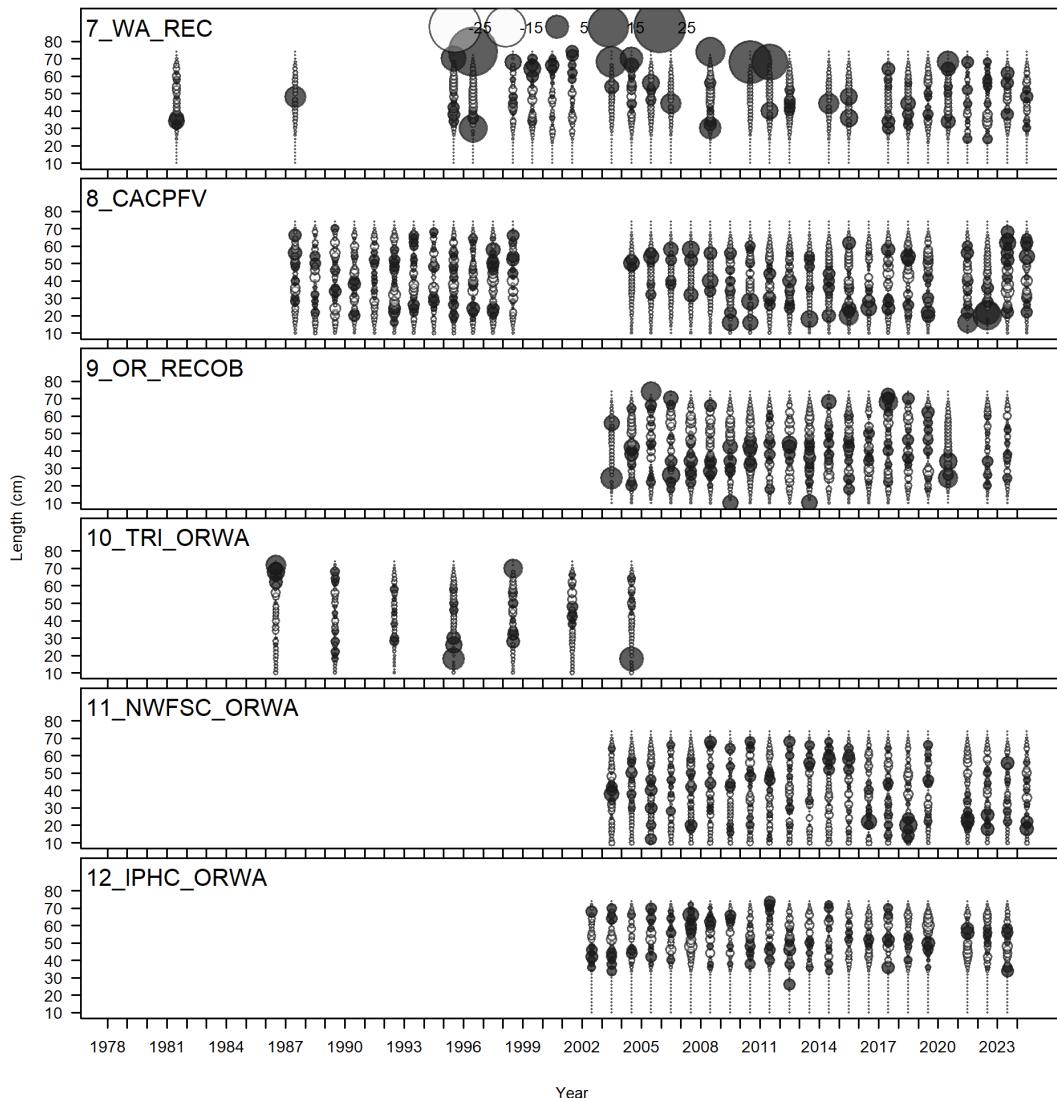

Figure 47: Pearson residuals, comparing across fleets, for length composition data (2 of 2). Closed bubbles are positive residuals (observed > expected) and open bubbles are negative residuals (observed < expected).

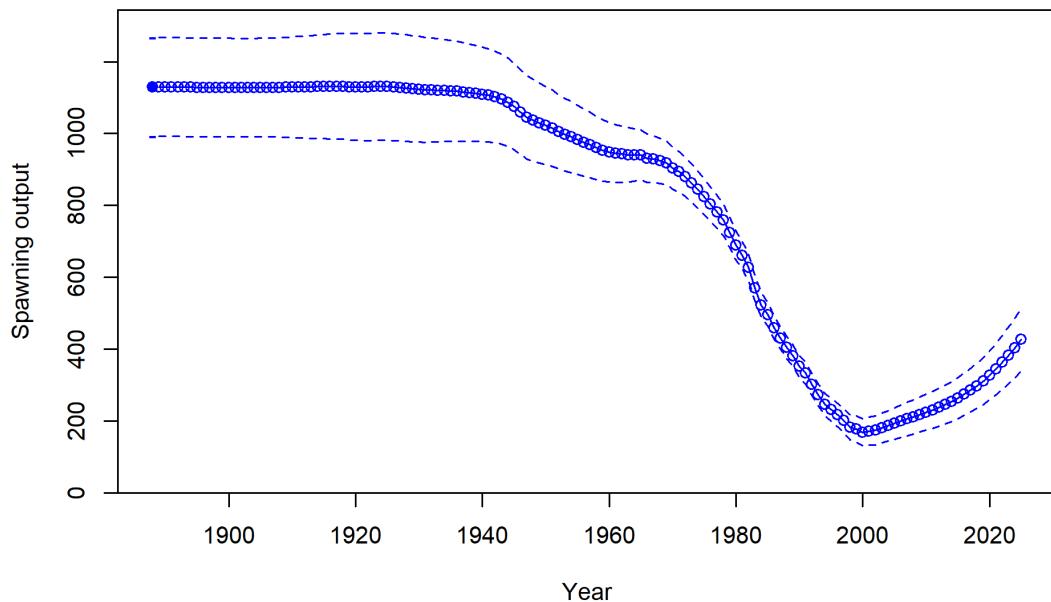

Figure 48: Estimated spawning output over time for both areas combined.

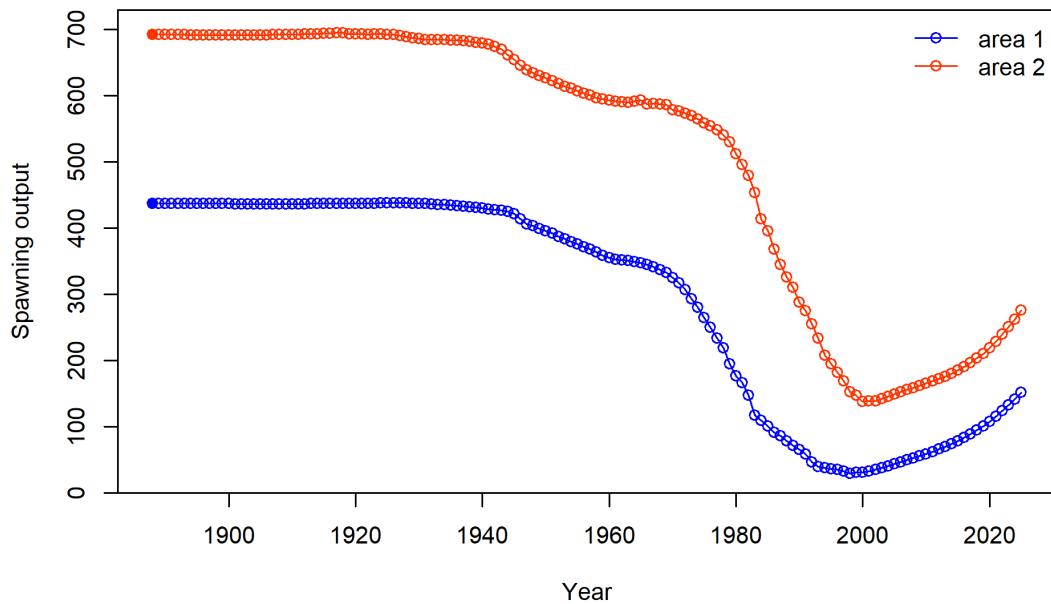

Figure 49: Estimated spawning output over time and by area (Area 1 is California, Area 2 is Oregon/Washington combined).

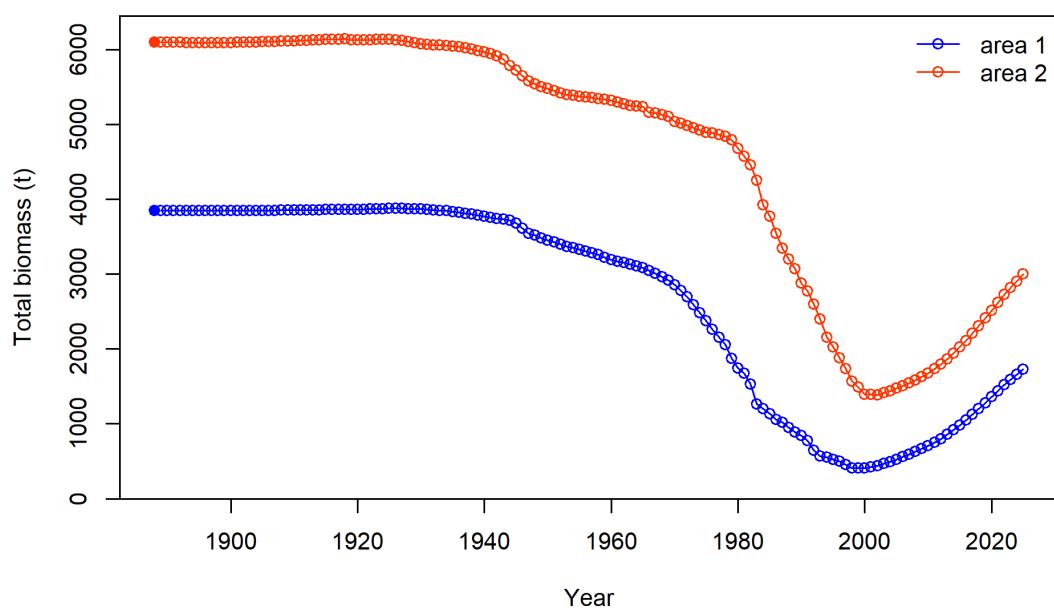

Figure 50: Total biomass (t) over time and by area (Area 1 is California, Area 2 is Oregon/Washington combined).

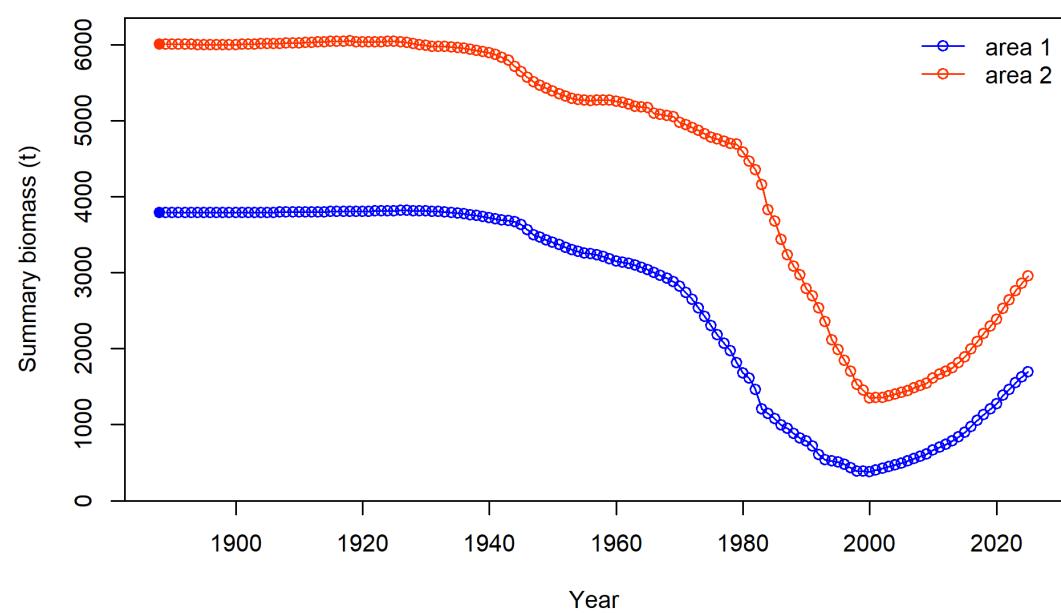

Figure 51: Summary biomass (t) over time and by area (Area 1 is California, Area 2 is Oregon/Washington combined).

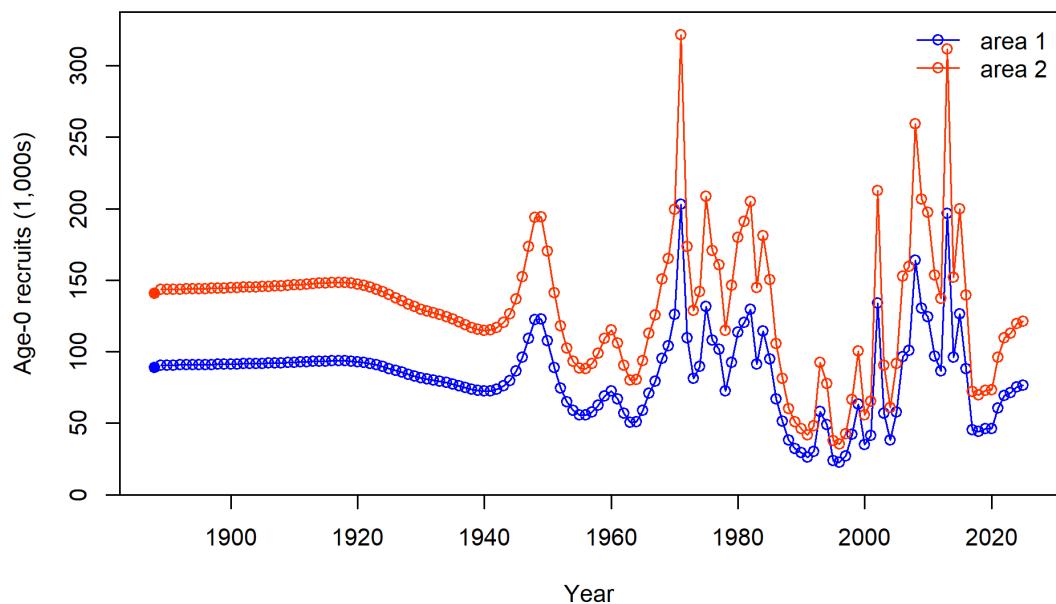

Figure 52: Age 0 recruits (1000s) over time and by area (Area 1 is California, Area 2 is Oregon/Washington combined).

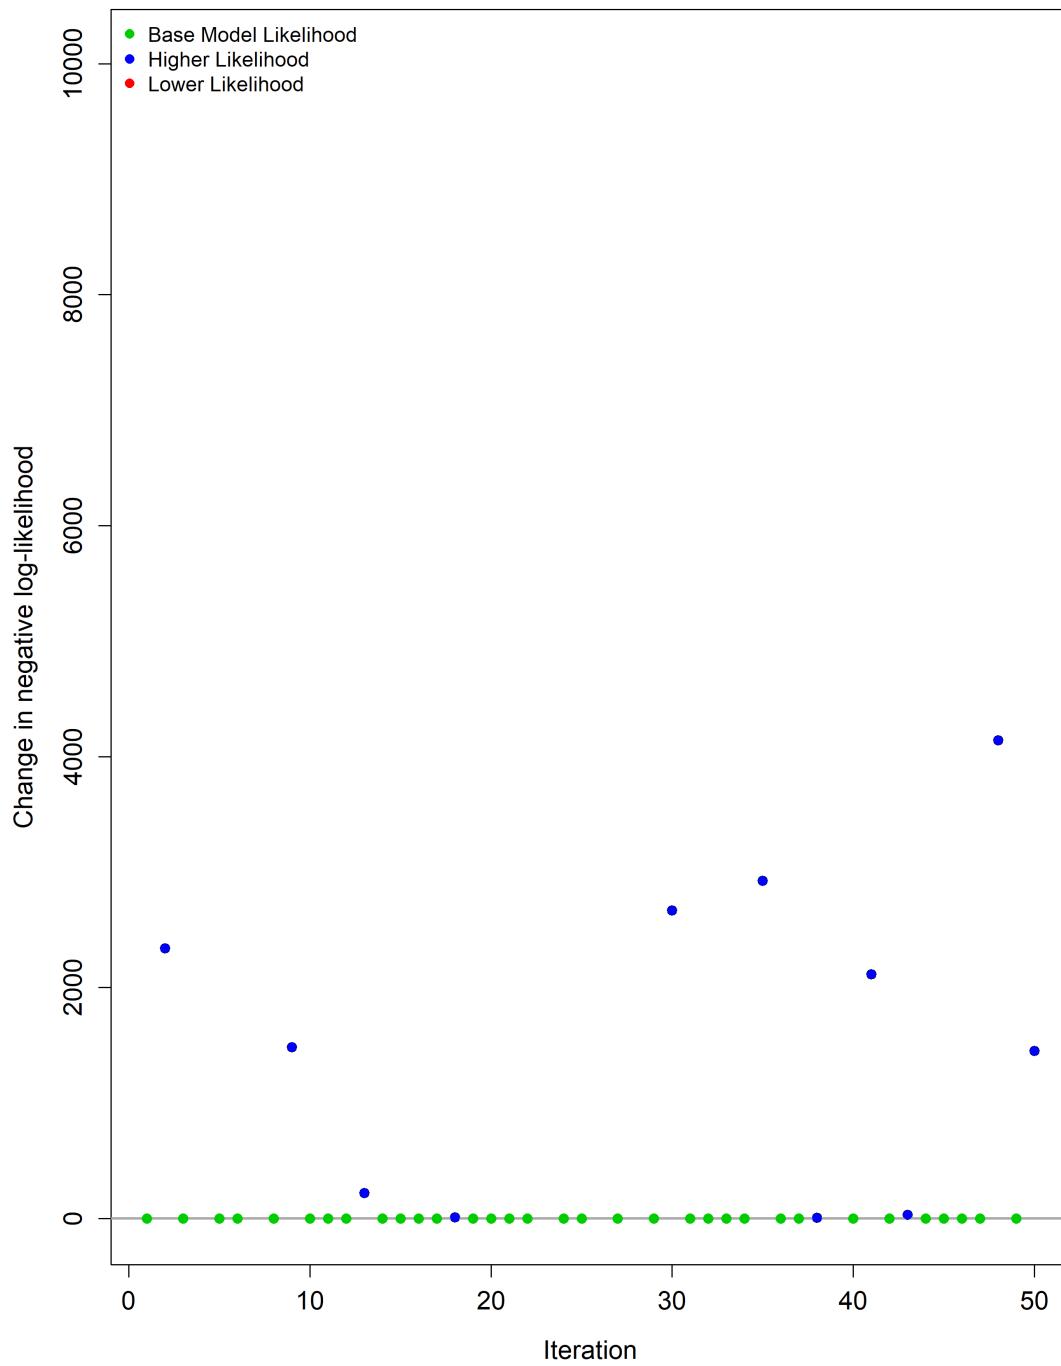

Figure 53: Results from 50 base model runs when starting parameters values are jittered by 0.1 units. Horizontal line indicates base model value.

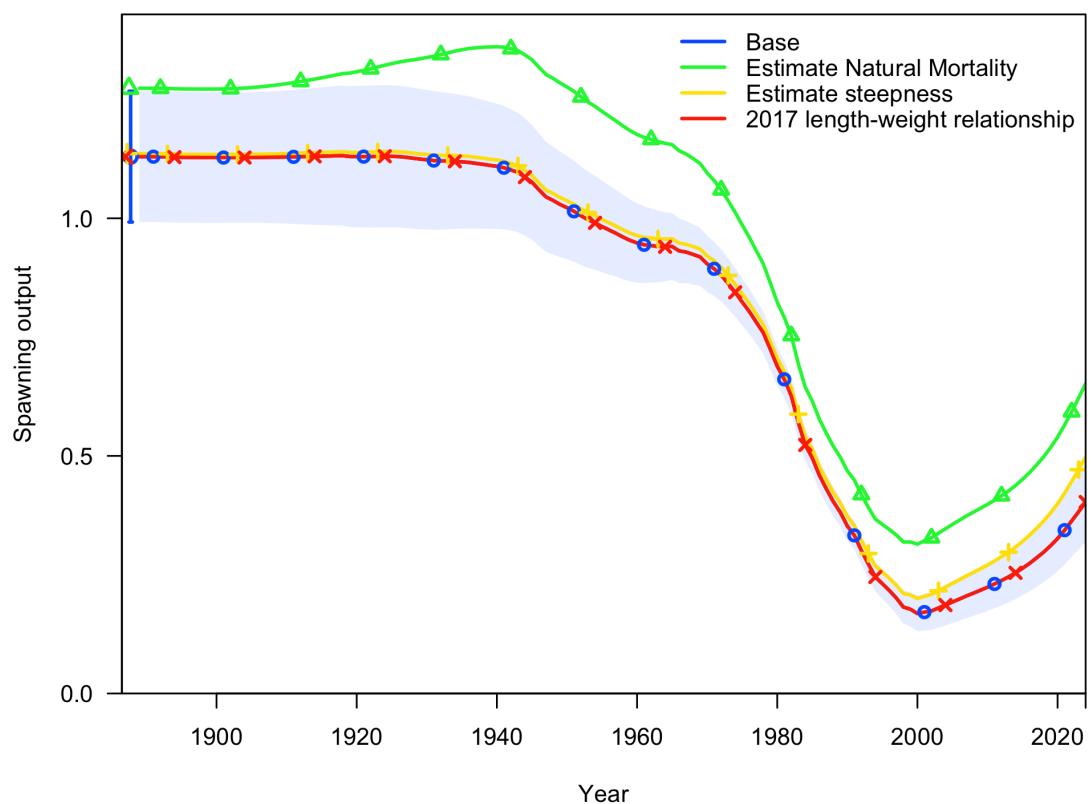

Figure 54: Spawning output across model structure sensitivities.

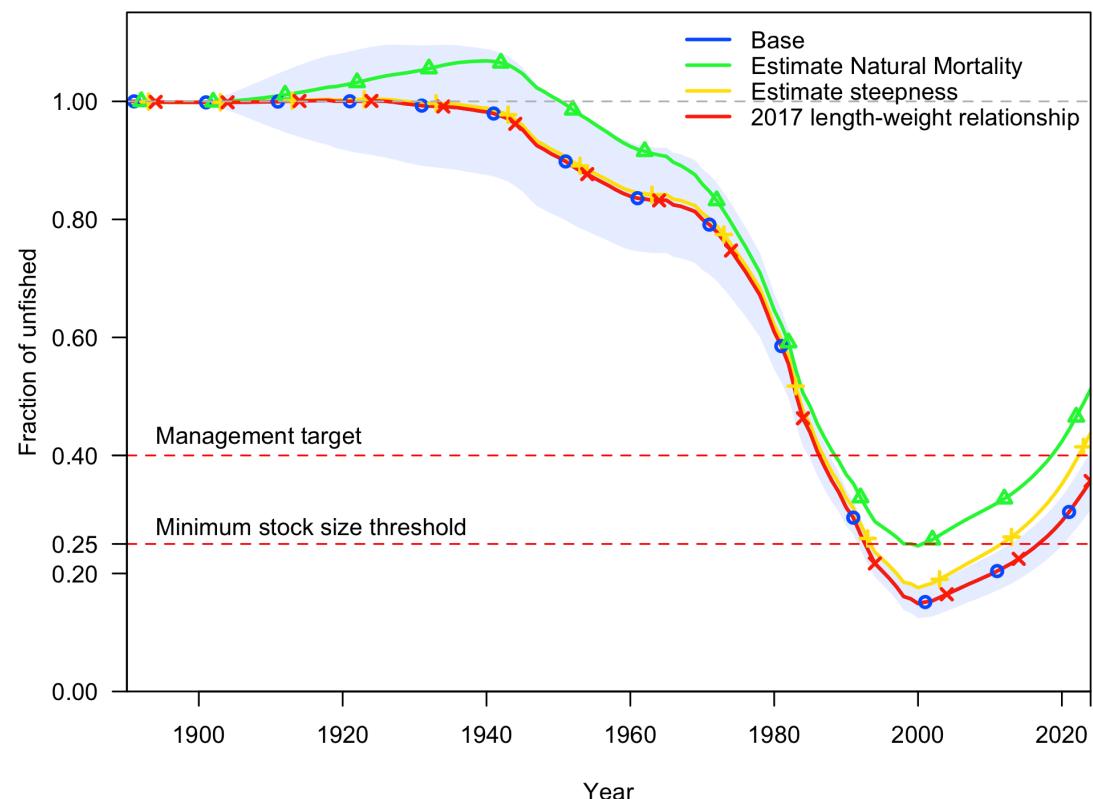

Figure 55: Relative spawning output across model structure sensitivities.

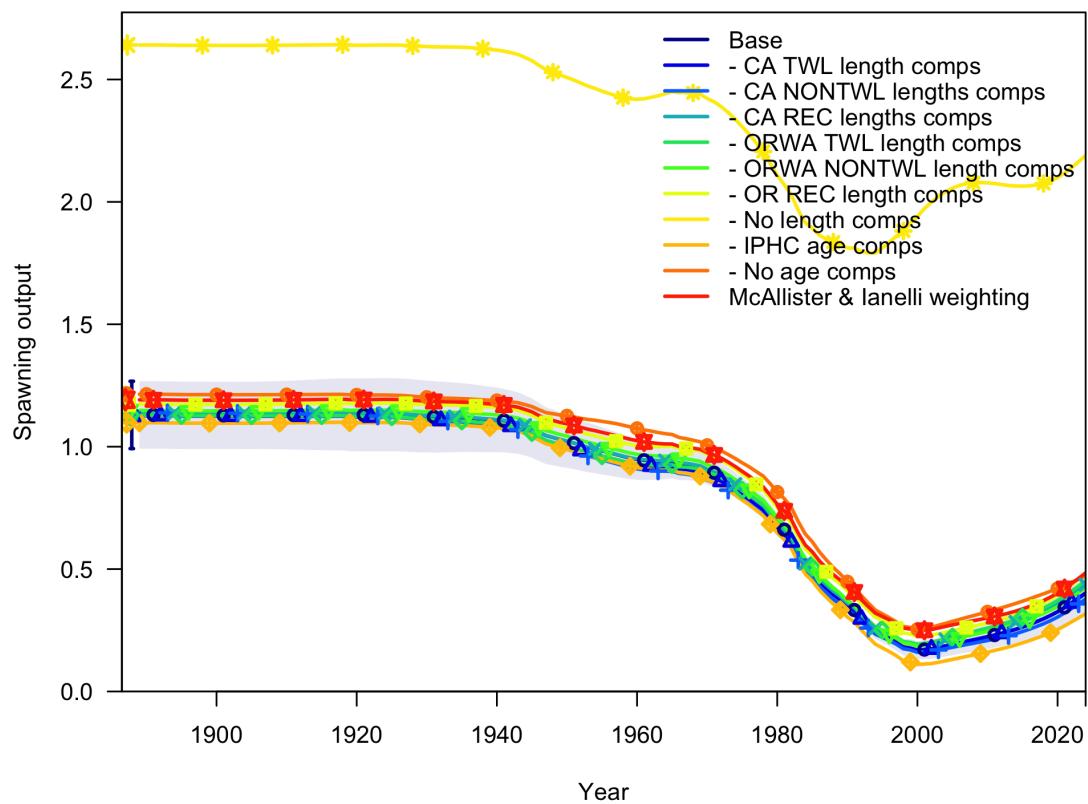

Figure 56: Spawning output across dataset inclusion sensitivities.

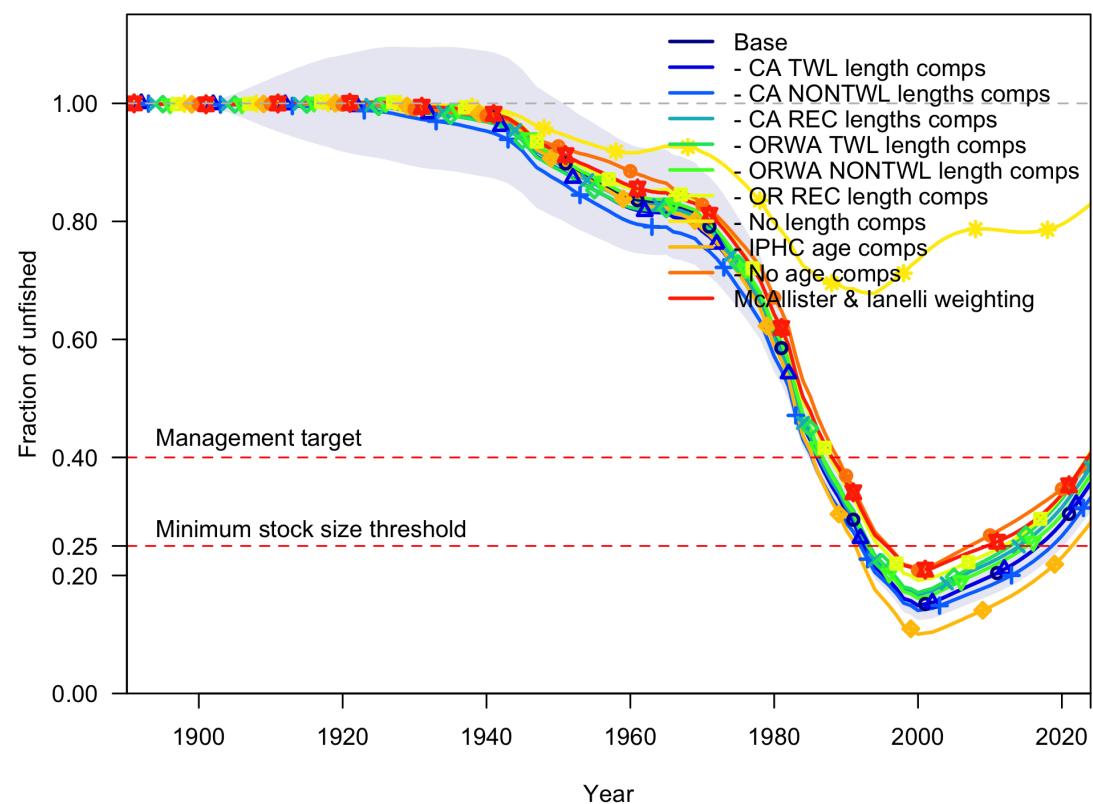

Figure 57: Relative spawning output across dataset inclusion sensitivities.

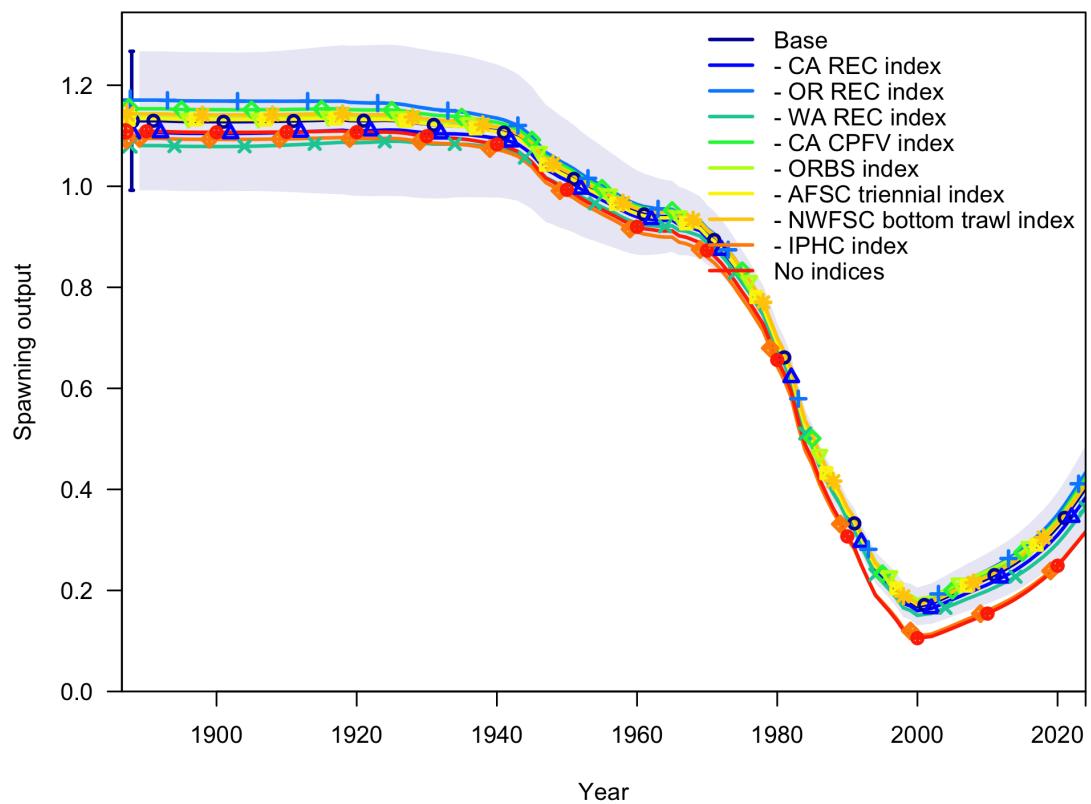

Figure 58: Spawning output across index inclusion sensitivities.

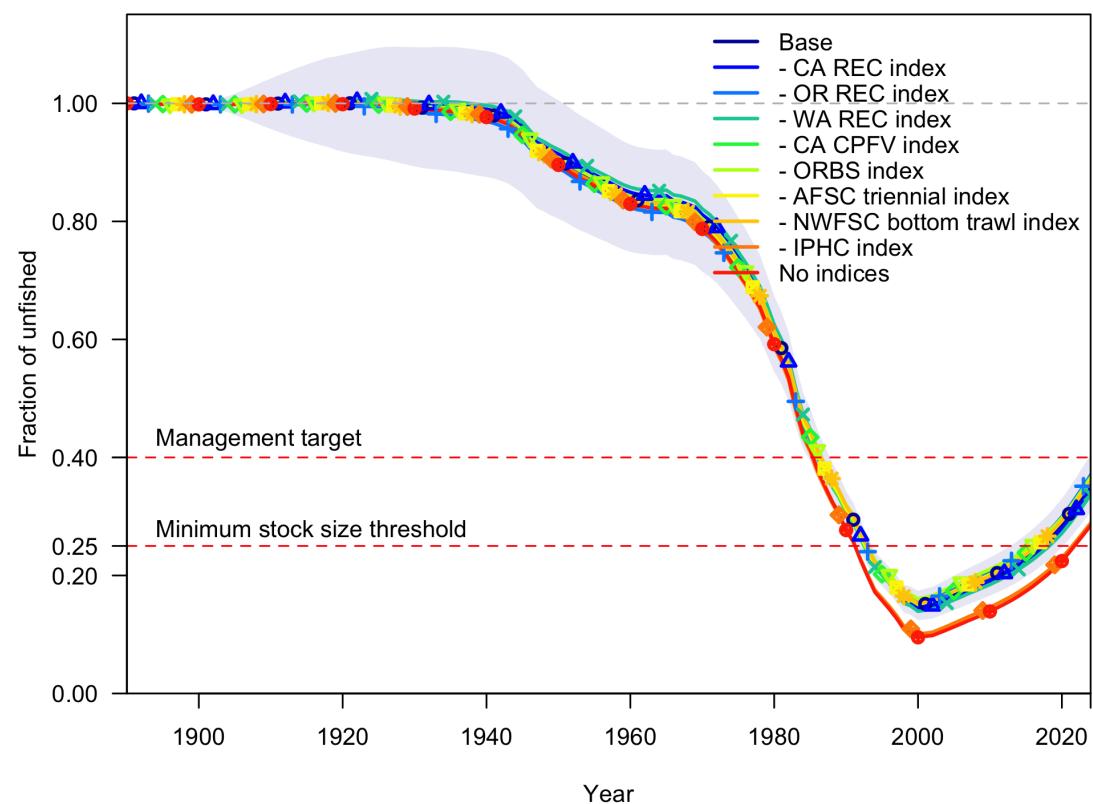

Figure 59: Relative spawning output across index inclusion sensitivities.

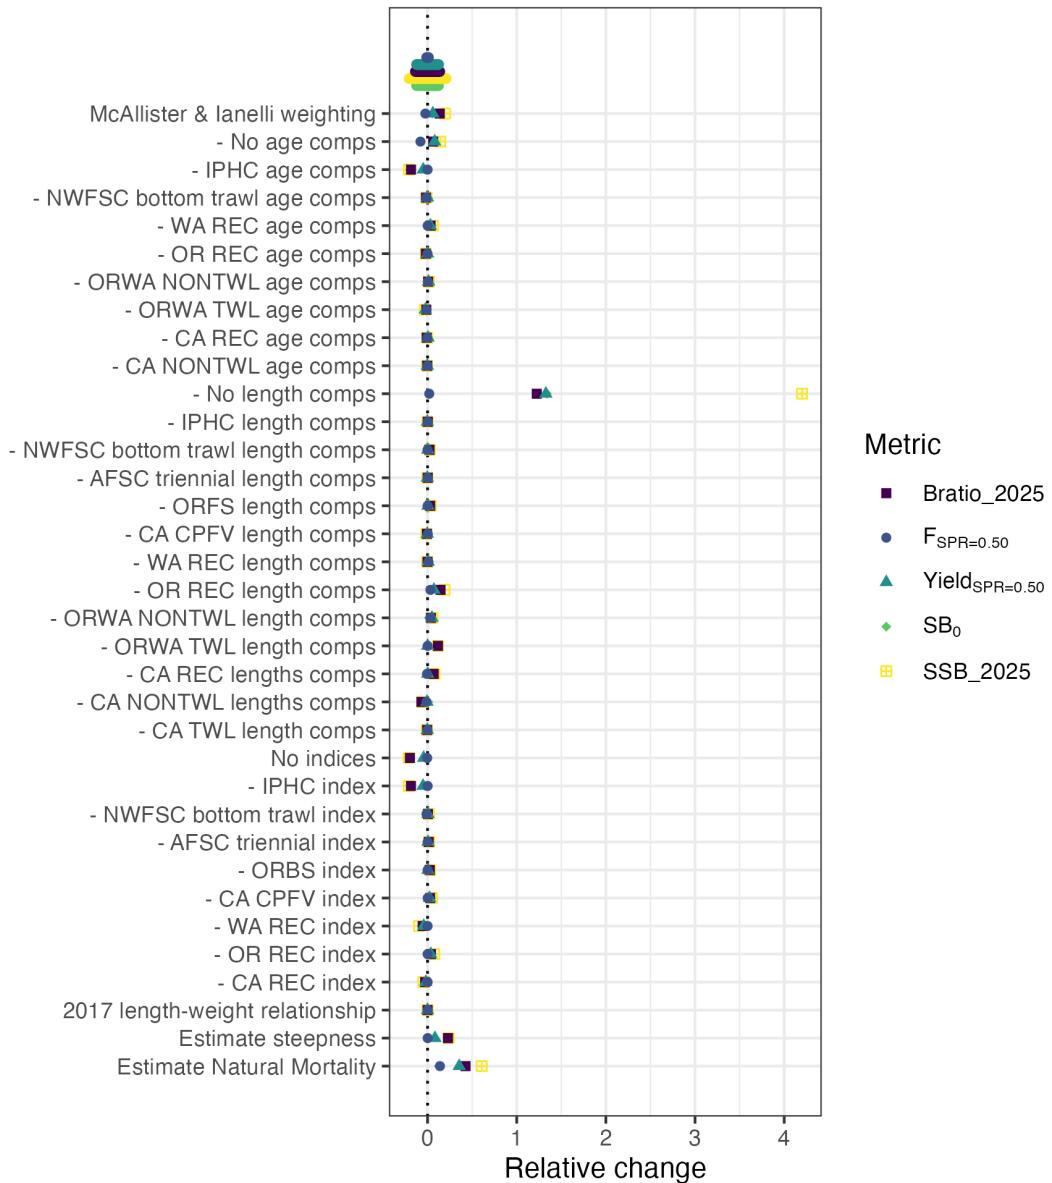

Figure 60: Relative change in management quantities across models conducted as sensitivities.

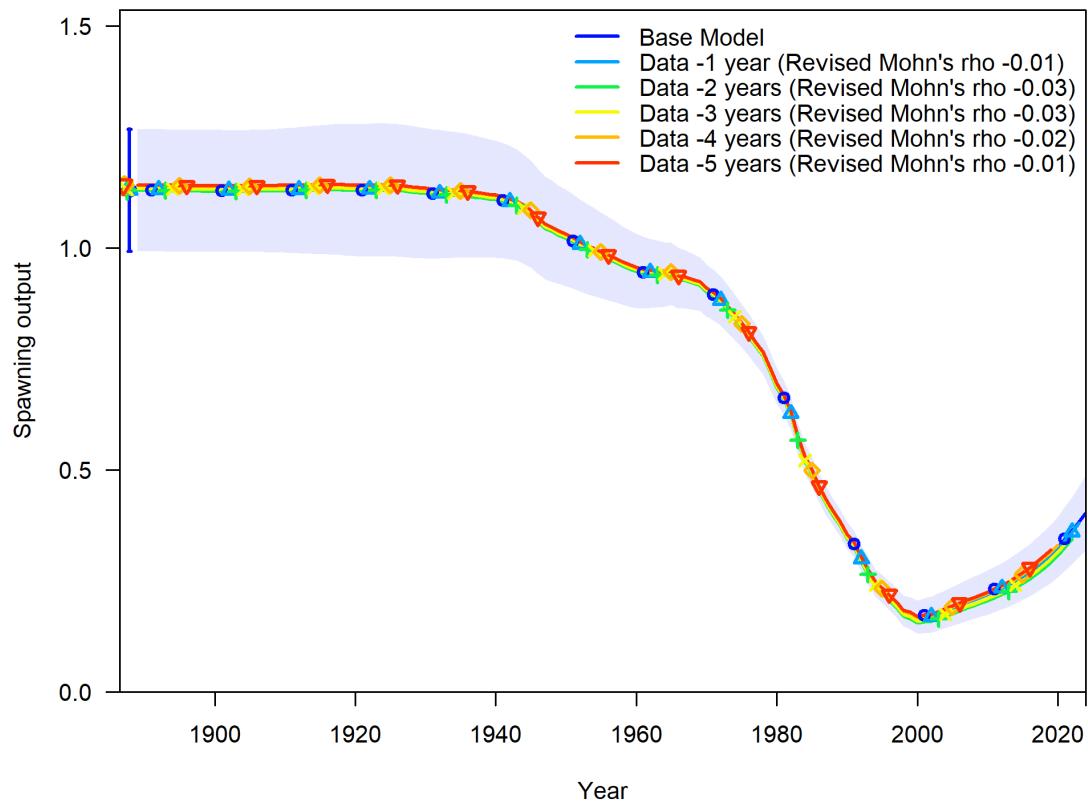

Figure 61: Results of retrospective analysis. Spawning output time series of this assessment base model are proved with ~95% interval.

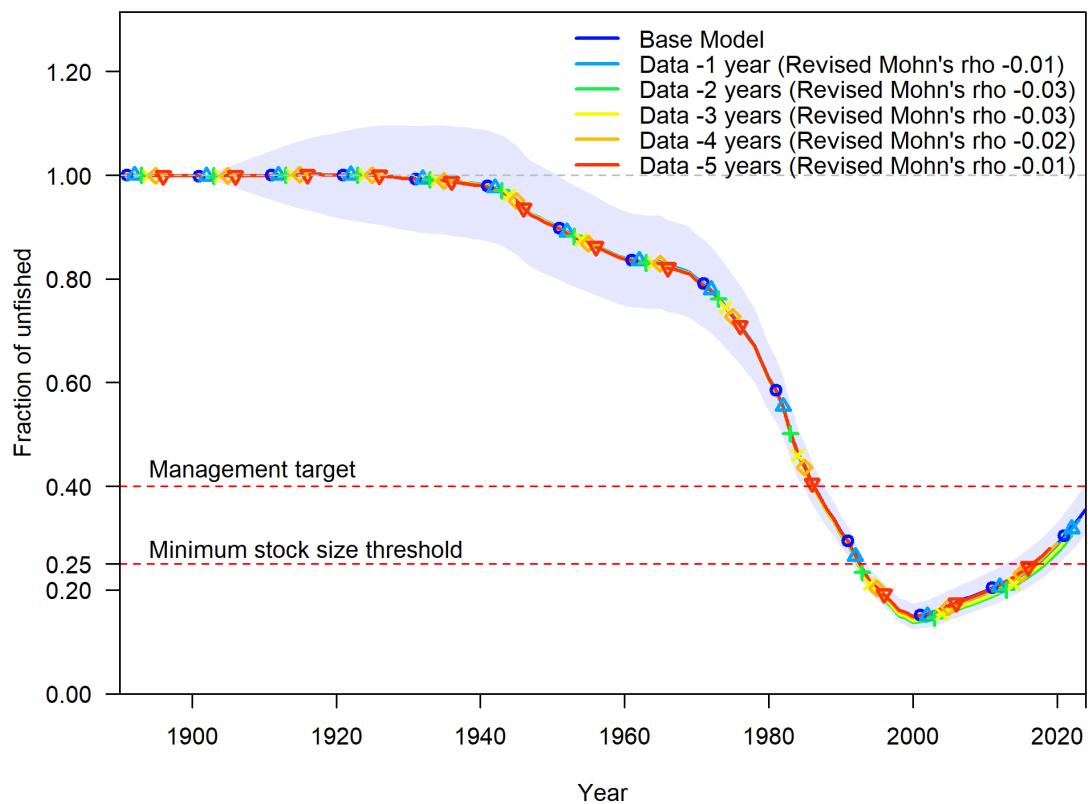

Figure 62: Results of retrospective analysis. Relative spawning output time series of this assessment base model are proved with ~95% interval.

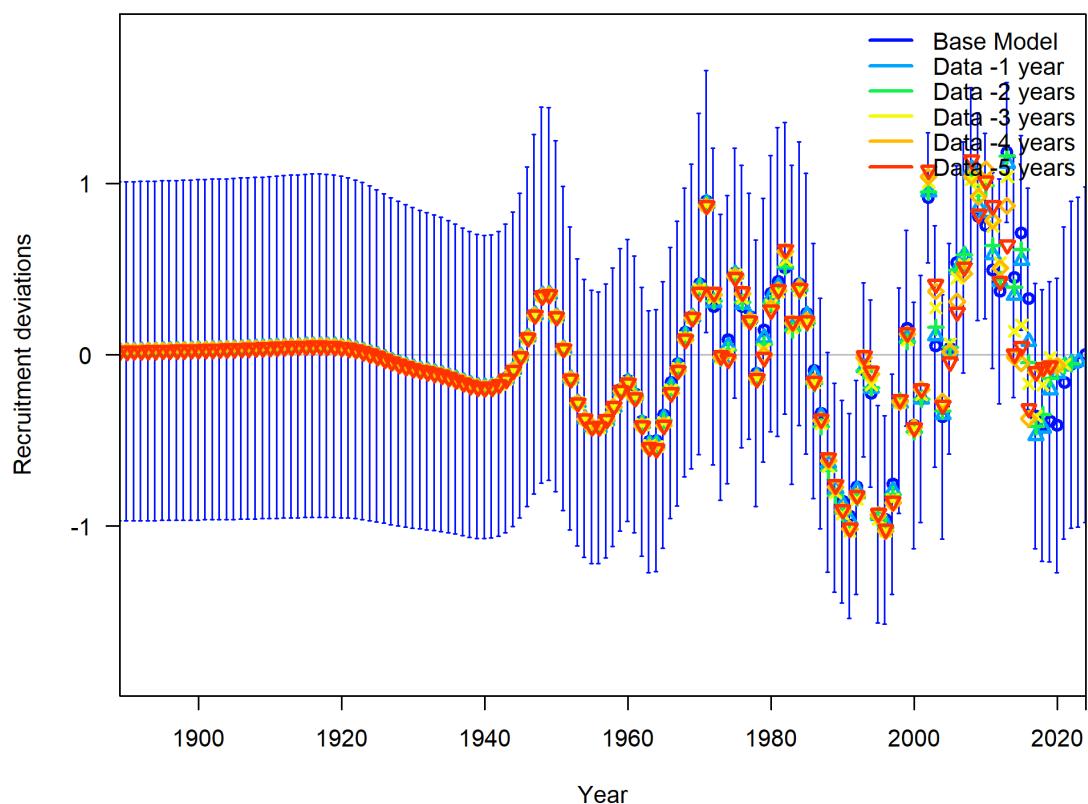

Figure 63: Recruitment deviation time series for each scenario of the retrospective analysis.

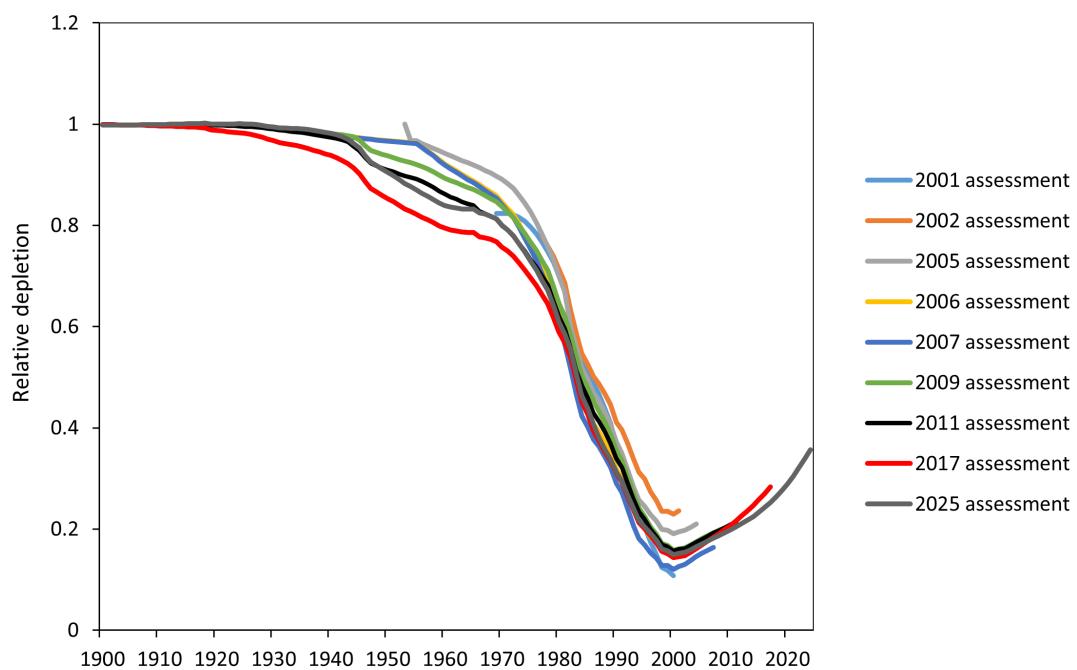

Figure 64: Relative depletion (spawning output) across Yelloweye Rockfish assessments over time.

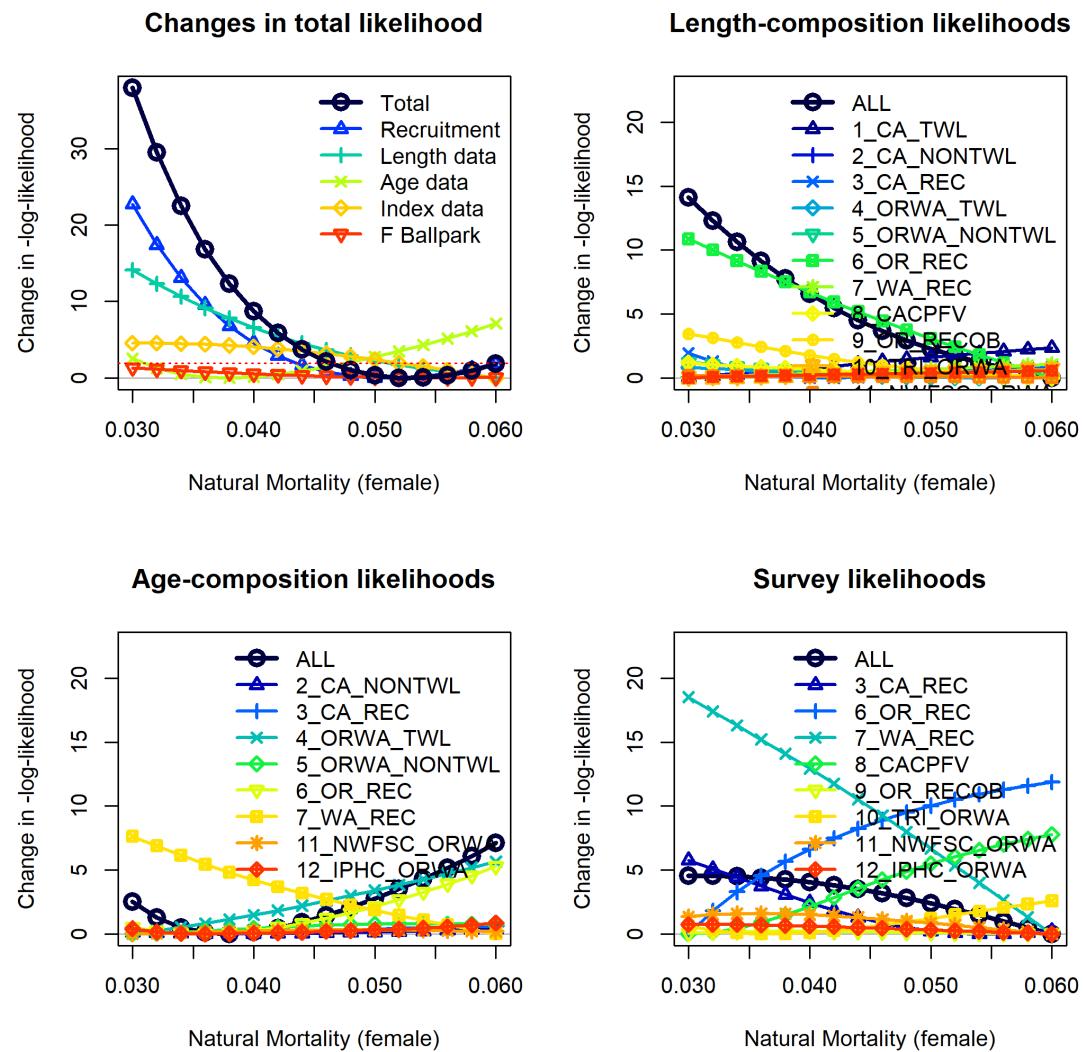

Figure 65: Negative log-likelihood profile for each data component and in total given different values of natural mortality ranging from 0.03 to 0.06 in increments of 0.002.

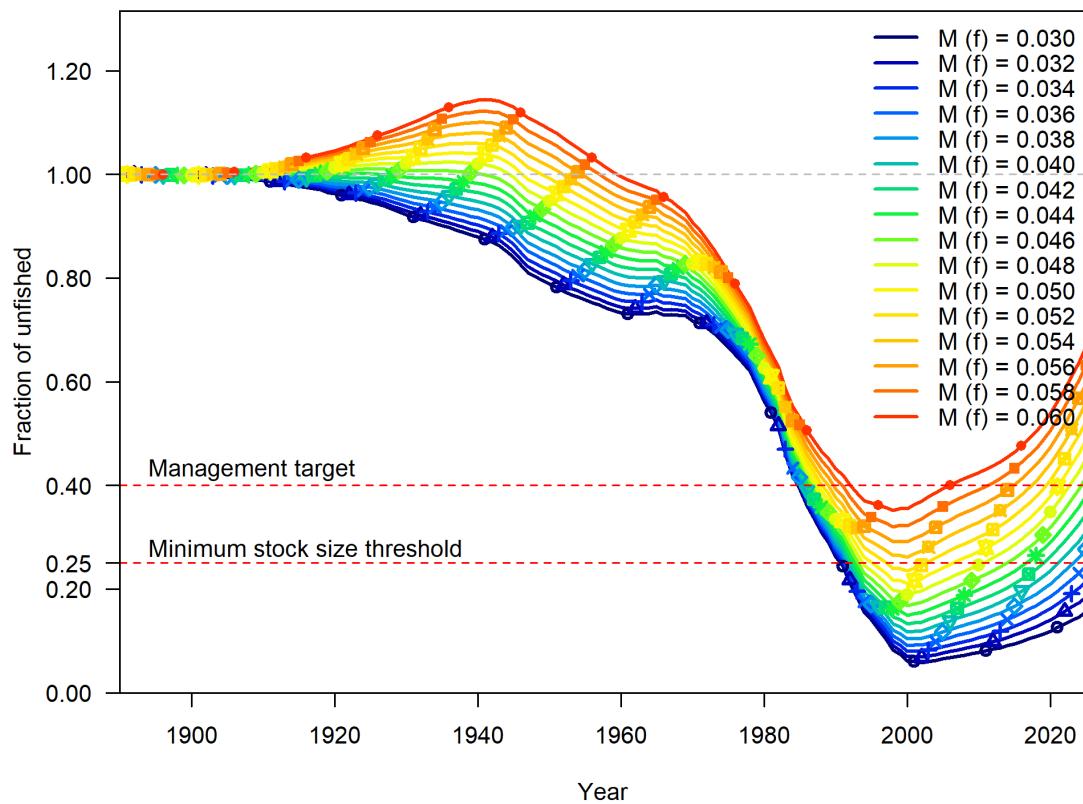

Figure 66: Time series of fraction of unfished biomass output associated with different values of natural mortality ranging from 0.03 to 0.06 in increments of 0.002.

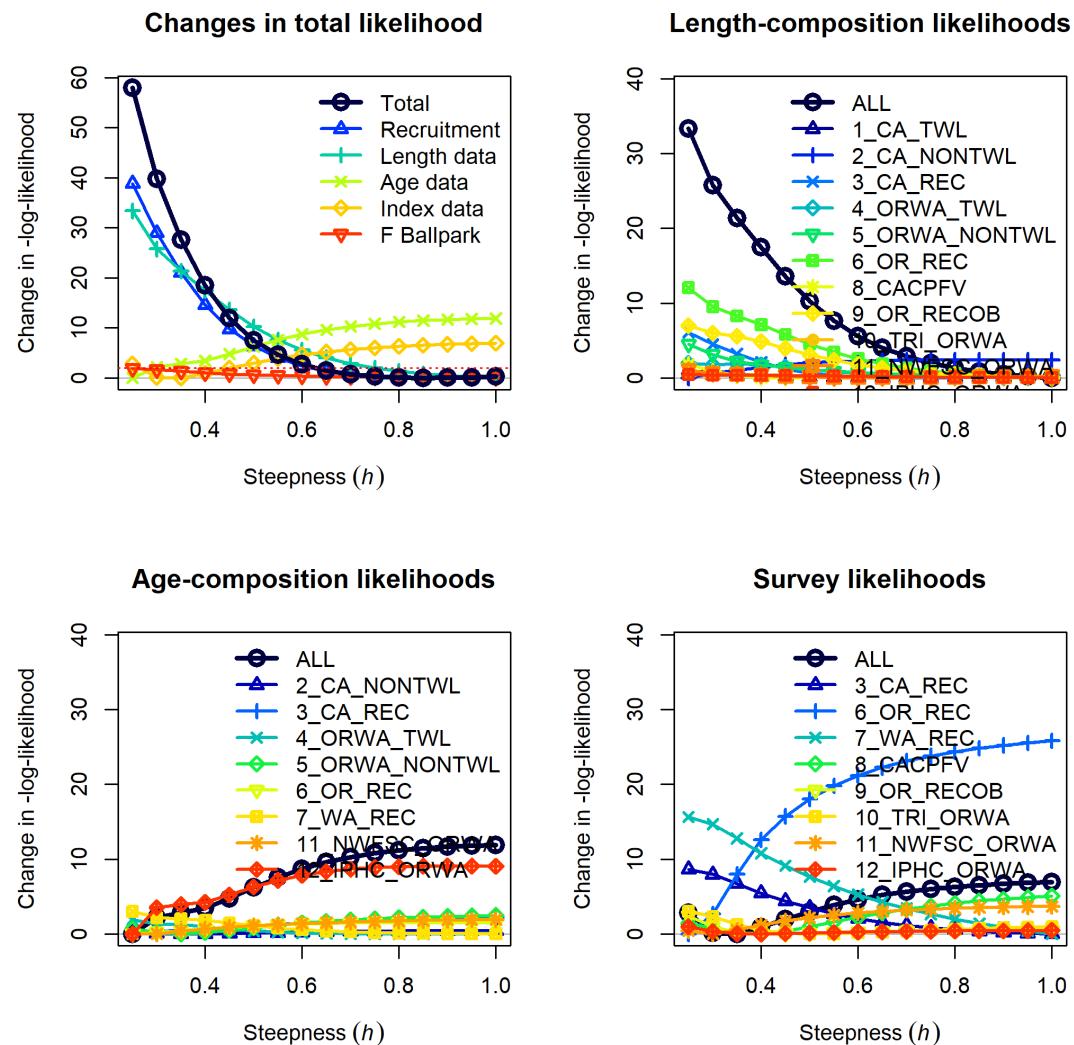

Figure 67: Negative log-likelihood profile for each data component and in total given different values of stock-recruit steepness ranging from 0.25 to 1.0 by increments of 0.05.

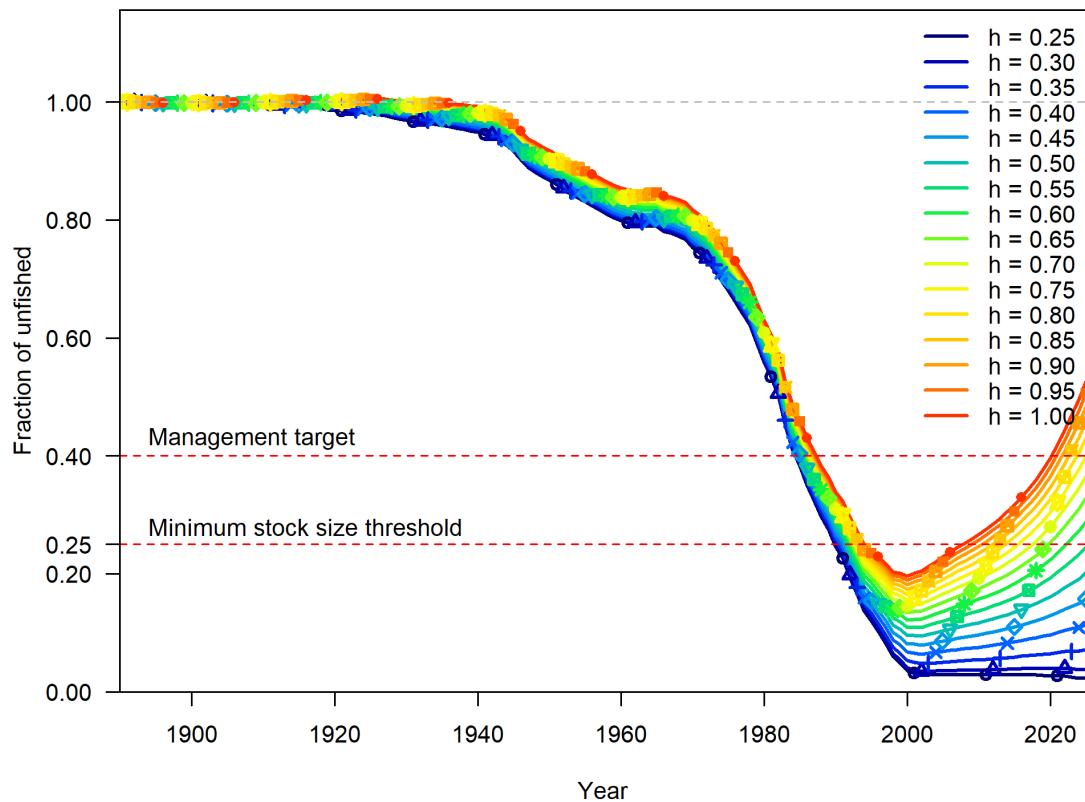

Figure 68: Time series of fraction of unfished biomass output associated with different values of steepness ranging from 0.25 to 1.0 in increments of 0.05.

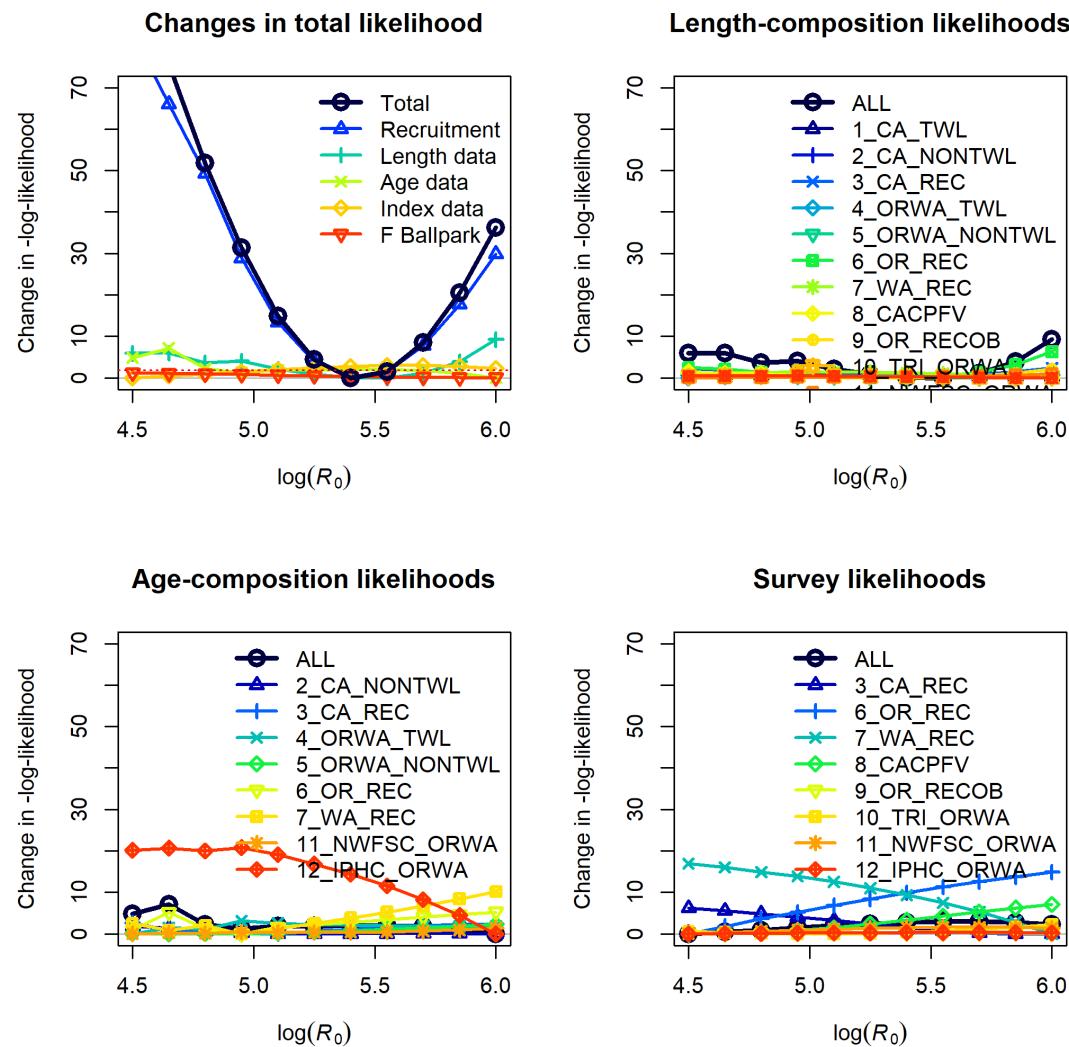

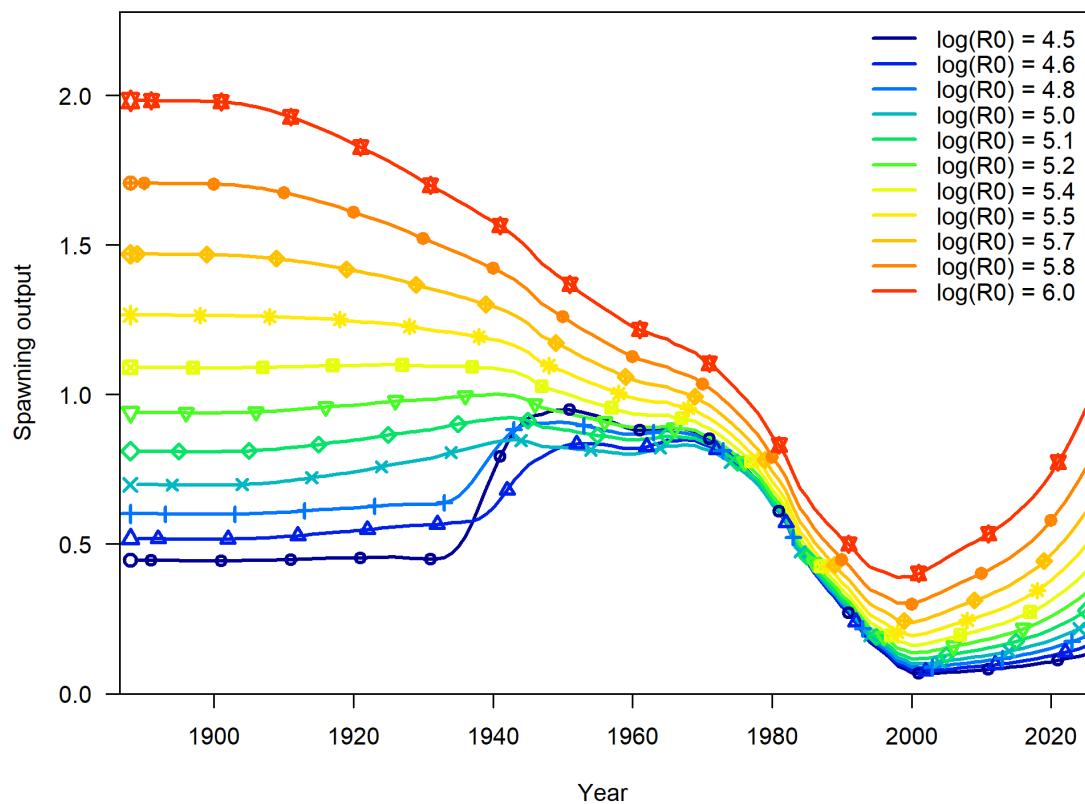

Figure 69: Negative log-likelihood profile for each data component and in total given different values of log initial recruitment ($\ln R_0$) ranging from 4.5 to 6.0 by increments of 0.15.

Figure 70: Spawning output as profiled over values of $\ln R_0$.

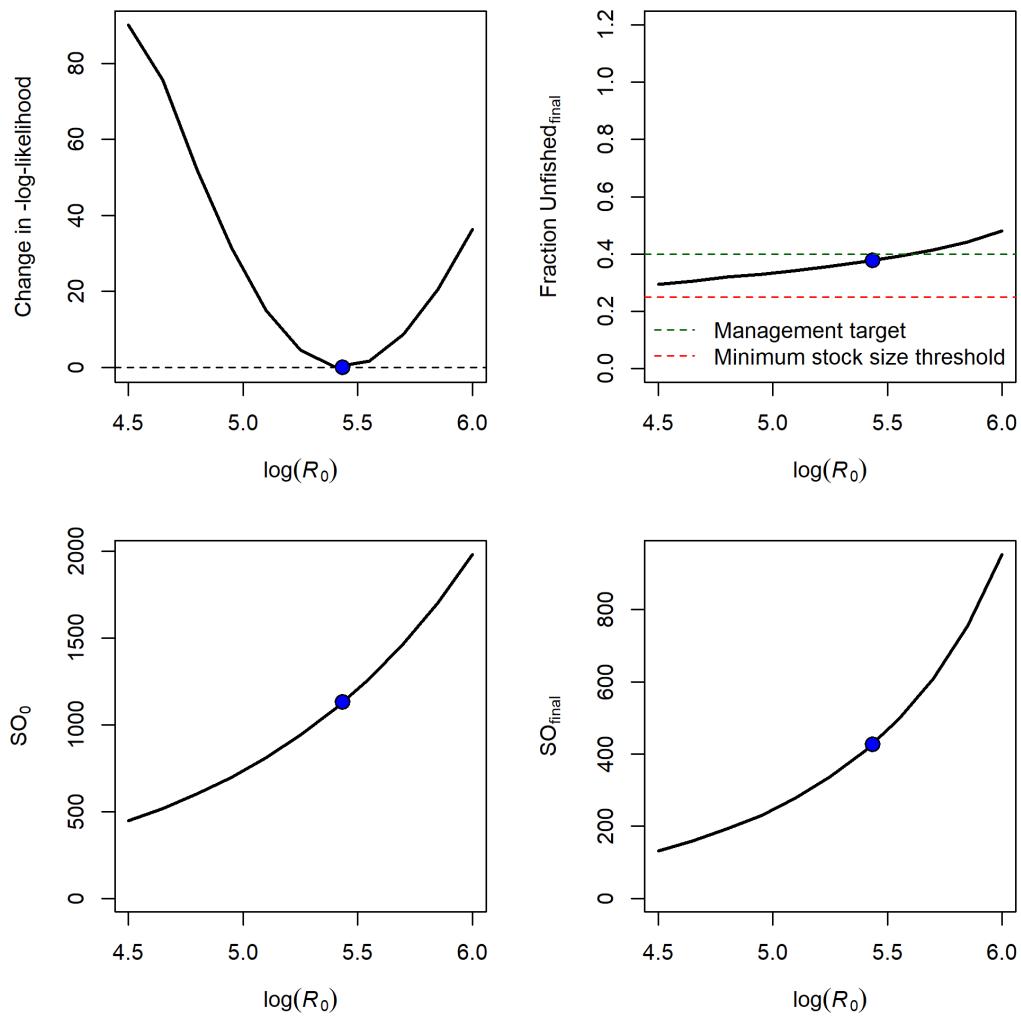

Figure 71: Likelihood profile (top left panel) for log initial recruitment ($\ln R_0$), with associated changes in stock status in the current year (SB_{2025}/SB_0 ; top right panel), initial spawning biomass (SB_0 ; bottom left panel), and current year spawning biomass (SB_{2025} ; bottom right panel). Points indicate the base model MLE estimate.

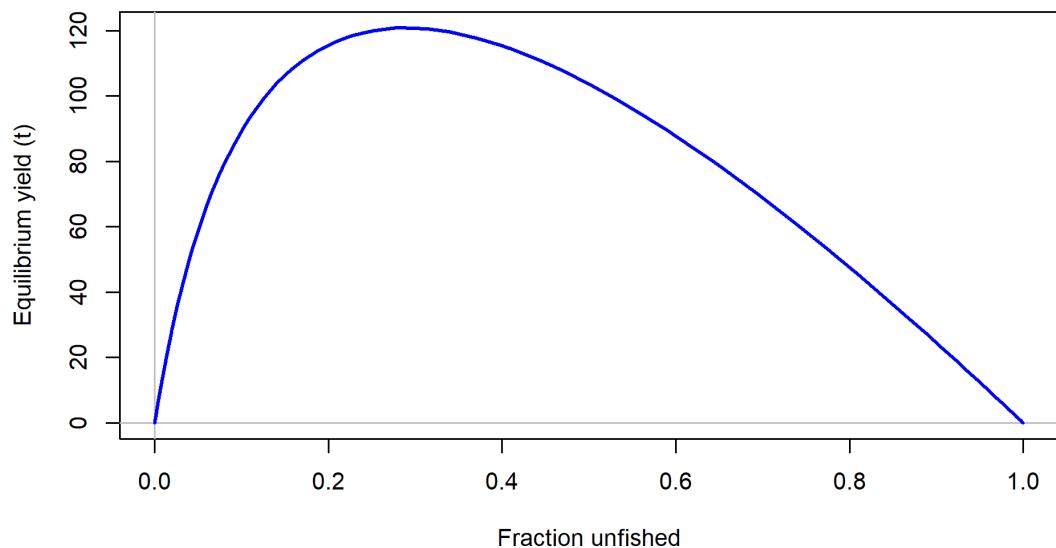

Figure 72: Equilibrium yield curve (derived from reference point values) for the base model. Values are based on 2024 fishery selectivity and distribution with steepness fixed at 0.718. The relative spawning output is relative to unfished spawning biomass.

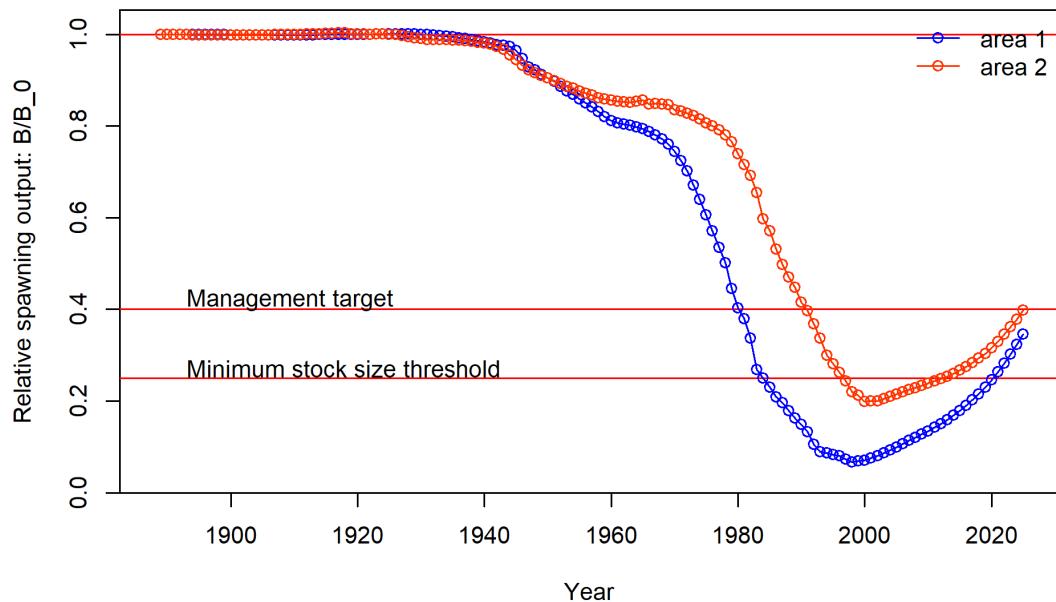

Figure 73: Time series of relative spawning output estimated by area (area 1= California, area 2 = Oregon and Washington).
